As further discussed subsequently, at any given time, only half of the sites in the active dimeric enzyme (in the *E. coli* enzyme, $\alpha_2\beta_2$) seem to be available for, for example, NADP(H) binding and reaction with dicyclohexylcarbodiimide. In a recent modification of this principle, an alternating site mechanism has been proposed in which the two dIIIs alternate between an open and a closed (occluded) state.

Membrane Topology and Helix Packing of the Membrane Domain

dII of the mitochondrial TH was earlier predicted to be composed of 14 transmembrane α -helices, whereas dII of the *E. coli* TH has been shown to be composed of 13 transmembrane α -helices (Figure 4). However, in contrast to the mitochondrial enzyme, *E. coli* TH consists of two subunits, the α - and β -subunits, both of which contribute to dII. For sometime, the membrane topology of the *E. coli* enzyme was unclear, especially regarding the region in dII where the two subunits interact. Subsequently, it was shown that the α - and β -subunits can be fused at the gene level, generating a mitochondrial-like TH, provided that the peptide linker is long enough, that is, as long as the extra helix peptide in the mitochondrial TH; shorter linkers lead to truncated proteins with diminished activities. The C terminus of the α -subunit and the N terminus of the β -subunit are therefore located on different sides of the membrane (Figure 4).

Despite the obvious importance of dII in the overall TH reaction, the structure of this domain has subsequently received comparatively little attention. However, a systematic effort to elucidate the packing of dII of the *E. coli* enzyme using cysteine cross-linking of double cysteine mutants in

the cysteine-free background has been carried out by Rydström and co-workers, with one cysteine located in the α -subunit and the other at various positions in the β -subunit. The results show that, within the $\alpha + \beta$ unit, helices 2 and 4 are close to helix 6, and helix 3 and the C terminus of the α -subunit are close to helix 7. In the $\alpha_2\beta_2$, helices 2 and 4, as well as helix 6, are close to the same helices in the second subunit.

The Proton Channel

Being a proton pump, the membrane domain of THs must contain at least one proton channel, and considering the symmetry of the active $\alpha_2\beta_2$ structure, most likely two identical channels, one in each β -subunit. That the channel resides in the β -subunit is obvious due to the lack of suitably conserved protonatable residues in the α -subunit. However, residues in the α -subunit may contribute to the proton channel. dII of the *E. coli* TH contains few conserved protonatable amino acids, which may form part of a proton channel. Based on the properties of especially the positively charged H91K and N222R mutants (mimicking protonated His91 and Asn222, respectively), located in helix 9 and helix 13 (Figure 4), Bragg and co-workers made the important discovery that these mutants contain tightly bound NADP(H), reminiscent of isolated dIII. Indeed, this was the first piece of evidence indicating that dII not only communicates with dIII, but that the degree of protonation of specific residues, that is, His91 and Asn222, in dII also induces conformational changes that affect the dissociation constant for binding of NADP(H) to dIII. Ser139 is another potential component of the proton channel, with Glu85, Asp213, and Glu124 being possible peripheral residues of the channel, located close to the membrane surfaces.

Some mutants of the conserved His91, Asn222, and Ser139 residues still catalyze proton pumping although at reduced rates. This may be due to a compensatory effect of the remaining protonatable residues in the channel. In this context, it should be stressed that a proton channel *per se* does not require

Figure 4 Membrane topology of *E. coli* TH. Residues in green background are at least 80% conserved among 61 THs. The topology was determined as described by Mueller J and Rydström J (1999) The membrane topology of proton-pumping *Escherichia coli* transhydrogenase determined by cysteine labeling. *Journal of Biological Chemistry* 274: 19072–19080.

protonatable residues. It would be sufficient with a chain of bound water molecules in a channel across the membrane to allow protons to jump from one water molecule to another. Protonation/deprotonation of protonatable amino acids in the channel induces conformational changes in the channel which link proton passage through the channel to catalytic events in often distantly located domains.

Coupling Mechanism

One of the main mechanistic challenges in past and present TH research is to understand how a Δp can be converted into a high $[NADPH][NAD^+]/[NADH][NADP^+]$ ratio and, conversely, how a high $[NADPH][NAD^+]/[NADH][NADP^+]$ (or a $[NADP^+][NADH]/[NADPH][NAD^+]$) ratio can drive proton pumping. Since the difference in standard redox potential between the NADPH/NADP⁺ and NADH/NAD⁺ pairs is negligible, the main contribution to the redox potential/free energy is derived from the above substrate/product ratios. Because of the water-soluble nature of the TH substrates, and the apparently large distance between the substrate-binding sites and the membrane, it has been generally accepted that some kind of conformational coupling is involved. Such a mechanism is often described as resembling that of adenosine triphosphatase (ATPase)/synthase in which conformationally dependent binding changes are essential. This was also experimentally demonstrated earlier by extensive Δp -dependent changes of K_m values for especially NAD(H). As described in the previous section, the single most important finding in this context was that mutating His91 and Asn222 to more positive amino acids leads to tightly bound NADP(H) in the intact mutant enzyme. An important contribution was also the demonstration of tightly bound NADP(H) in isolated dIII, which was assumed to represent an intermediate in the reaction cycle of TH, denoted the occluded state, which led to the proposal that both directions of the TH reaction, but especially the Δp -stimulated forward reaction, is limited by dissociation of NADP(H). The term 'binding change' mechanism is frequently used in order to stress the role of dissociation/binding of NADP(H).

Despite the known crystal structures of dI, dIII, and the dI–dIII complex, the interface between dII and dI + dIII is unknown, that is, little is known regarding the communication between dII and dIII. Most cytosolic loops of dII are poorly conserved, which makes it unlikely that dII–dIII signaling occurs via the surfaces of these domains. However, the peptide linking the C-terminal end of dII with dIII is quite conserved, and is highly mobile during catalysis as indicated by the NADP(H)-dependent increased trypsin sensitivity of Arg265 close to transmembrane helix 14 (Figure 4), indicating that this region is potentially important. Subsequently, Arg265 has been suggested to form a functional salt bridge with Asp213, constituting an essential component (hinge region) of a new coupling mechanism. However, communication between this proposed salt bridge and the NADP(H)-binding site remains unknown, although loops D and E close to the NADP(H)-binding site in dIII may be important. As already mentioned, proton-translocating THs, which are all dimers, may work according to an alternate-site-binding change mechanism. According to this mechanism, only half of the intact TH is catalytically active at any given time.

Physiological Role

In 1959, Klingenberg and Slenczka found that the mitochondrial redox level of NADP(H) was at least 90%, and that of NAD(H) ~50–60%. The forward TH reaction (reaction [1]), driven by Δp , is largely responsible for this high redox level of NADPH which, as expected, is sensitive to uncouplers. This also explains the fact that NADPH-dependent detoxification (through glutathione peroxidase, glutathione reductase, and reduced glutathione) of organic peroxides in intact mitochondria is more effective with NADH-linked substrates than with NADPH-linked substrates. Thus, endogenous NADP⁺ together with NADH (generated by the added substrate, e.g., β -hydroxybutyrate) provides a higher redox level of NADPH through TH than NADPH-linked substrates. NADPH also regulates the redox levels of thioredoxin and protein-bound thiols. Organic peroxides generated by, for example, oxidative stress, lead to a rapid oxidation of mitochondrial-reduced glutathione through the glutathione peroxidase system, which, in turn, leads to a massive release of Ca²⁺ ions, presumably through mitochondrial anion channels, for example, the inner mitochondrial anion channel (IMAC) and the permeability transition pore (MPTP). These channels may, in turn, contain redox-sensitive protein thiols. Therefore, the high mitochondrial redox level of NADP(H), maintained by TH, is of crucial importance for detoxification, Ca²⁺ homeostasis, cell thiol regulation, and biosynthesis. In liver, but probably not in heart, TH-generated NADPH in the mitochondrion contributes to cytosolic NADPH through transport in the form of (iso)citrate generated by the NADP-dependent isocitrate dehydrogenase (NADP-ICDH). That TH indeed regulates the redox level of the glutathione pool and, thus the defense against oxidative stress, was demonstrated using a knockout of TH in the nematode *C. elegans*.

A different hypothesis for the physiological role of TH involves a regulation of the citric acid cycle, especially the NAD and the NADP-dependent isocitrate dehydrogenases. The NAD enzyme (NAD-ICDH) is irreversible and strongly regulated by, for example, adenosine diphosphate, whereas NADP-ICDH is reversible and apparently unregulated. Oxidative decarboxylation of isocitrate to α -ketoglutarate, carbon dioxide, and NADH by the NAD-ICDH can be linked to the NADP-ICDH by a reductive carboxylation of α -ketoglutarate, carbon dioxide, and NADPH back to isocitrate. The NADH generated by the NAD-ICDH, together with NADP⁺, is thus used by TH and Δp to generate NADPH that drives the NADP-ICDH. This nonproductive cycle uses one proton/cycle to slow down or regulate the flux through this step in the citric acid cycle. However, there is no obligatory simultaneous occurrence of TH and NADP-isocitrate dehydrogenase in some species, which casts some doubt on this potentially important regulatory system.

Theoretically, a reversal of reaction [1] can also be used to generate a Δp under, for example, ischemic conditions. However, it is generally believed that unless a continuous source of NADP⁺-reducing substrates as well as NAD⁺-oxidizing substrates are available, the Δp generated would be transient and short lived.

More recently, the C57BL/6J mouse strain has been shown to be a natural/spontaneous knockout of the TH gene (nicotinamide nucleotide transhydrogenase (NNT)). These mice

show a number of interesting properties such as glucose intolerance, that is, a decreased insulin production in response to a glucose load, reminiscent of a diabetes-like condition, a decreased cancer frequency, decreased resistance to oxidative stress, and obesity. Knockout of the mitochondrial superoxide dismutase (SOD2) in the C57BL/6J background results in mice with severely decreased heart function and a life span of only 1–2 days.

Glossary

Domain A compact region of protein structure that is a stable entity.

Heterodimer A protein composed of two nonidentical subunits.

Kinase An enzyme that transfers a phosphoryl group from a donor (typically adenosine triphosphate) to

an acceptor (often a protein in cell signaling pathways).

Neurotransmitter A chemical messenger released or synthesized at a synapse.

Phosphatase An enzyme that removes a phosphoryl group.

Radical A chemical species with an unpaired electron.

The basic components of nitric oxide (NO) signaling involve nitric oxide synthase (NOS) to synthesize NO and the soluble isoform of guanylate cyclase (sGC) to trap NO. Once activated by NO, sGC converts guanosine triphosphate (GTP) to guanosine 3'/5'-cyclic monophosphate (cGMP), leading to cGMP-dependent physiological responses such as vasodilation. Termination of the cGMP signal involves a cyclic nucleotide phosphodiesterase (PDE). There are multiple PDE isoforms, and selective inhibition of specific isoforms has proven to be clinically useful (e.g. sildenafil (viagra) in the treatment of erectile dysfunction). sGC must also be turned off; however, the *in vivo* mechanism for this remains unknown. Catalytic activity of constitutive NOS isoforms involved in signaling is controlled by Ca^{2+} and calmodulin (CaM) via receptor-mediated events that trigger Ca^{2+} release from intracellular stores or uptake from external sources.

Biological Processes Controlled by NO

First defined as endothelium-derived relaxing factor, the biological effects of NO have now been definitively characterized in a number of tissues. Smooth muscle is often the target of NO action, leading to vasodilation in blood vessels (Figure 1) and penile erection via NO synthesis in the corpus cavernosum, two well-established functions. Smooth muscle relaxation in the gut is another important function for NO, playing a key role in gastrointestinal tract motility. NO synthesis in the brain is also well established, though the exact role in learning and memory is still under debate. In the central nervous system (CNS), NO acts as a somewhat atypical neurotransmitter in that it is not synthesized and stored and then released with the appropriate signal, but is synthesized on demand. Constitutive NOSs are involved in all of these responses and are under the control of Ca^{2+} and CaM. Receptor-mediated events that trigger Ca^{2+} release or uptake turn on the specific NOS isoform in the tissue. NOS has also been found in skeletal muscle, in the myocardium, and in many other cells, suggesting that it will play an even more extensive role in physiological control than is currently established. The function of NO in the myocardium is particularly complex, although it appears that novel therapeutics will be an outcome of sorting out the complexity.

NO Synthase

The catalytic activity of the NOS isoforms (constitutive) involved in signaling is controlled by Ca^{2+} and CaM. After stimulation by the appropriate external signal, an increase in intracellular-free Ca^{2+} occurs, which then leads to a Ca^{2+} –CaM complex. Each of the four EF hands of CaM binds one Ca^{2+} , and then this Ca^{2+} –CaM complex binds to NOS, thereby activating NOS to synthesize NO. The NOS reaction is shown in Figure 2. The enzyme converts L-arginine to citrulline and NO. Co-substrates for the reaction include nicotinamide adenine dinucleotide phosphate-oxidase (NADPH) and O_2 . NOS is composed of two domains: a reductase domain with homology to cytochrome P450 reductase and a heme domain. The reductase domain contains two bound flavins, flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN), and with analogy to P450 reductase, the electron transfer route is from NADPH to FAD and then to FMN. The heme domain contains a cytochrome P450-type heme (ferric protoporphyrin IX coordinated to cysteine thiol), one equivalent of 6(R)-tetrahydro-L-biopterin (H_4B), and the L-arginine binding site. Crystal structures of the heme domain show it to be dimeric with a tetra-thiolate zinc center at the dimeric interface using two cysteines from each subunit. Catalytic chemistry at the heme domain is dependent on electron transfer from the flavins in the reductase domain, which is triggered by binding of the Ca^{2+} –CaM complex to NOS.

The catalytic chemistry takes place at the P450 heme site; in fact, structures of the oxygenase domain that have been solved in the presence of L-arginine show the substrate positioned over the heme. H_4B also participates in electron transfer at the heme site, using unprecedented one-electron chemistry. The exact details of the involvement of this required bound cofactor are still emerging. As shown in Figure 2, L-arginine is first converted to N^G-hydroxy-L-arginine (NHA) and then NHA is converted to citrulline and NO. NADPH and O_2 are required in both steps of the reactions, as is H_4B . The mechanism of the reaction is complicated and not fully understood, but clearly involves oxidative chemistry at the P450 heme with participation of H_4B .

The Ca^{2+} –CaM complex exerts control over the NOS reaction catalyzed by the constitutive cell-signaling isoforms,

Figure 1 Nitric oxide function in blood vessel dilation. In response to a receptor-mediated event (shown schematically), endothelial NOS is activated by Ca^{2+} and CaM, leading to the synthesis of NO. NO then diffuses into the adjacent smooth muscle and activates the soluble isoform of guanylate cyclase and the synthesis of cGMP. cGMP, through a signaling cascade, then leads to smooth muscle relaxation.

Figure 2 The reaction catalyzed by nitric oxide synthase. The substrate for the reaction is the amino acid L-arginine, which is converted to L-NHA and then to citrulline and $\bullet\text{NO}$. Although it has never been shown, it is assumed that the stereochemistry of citrulline at the α -carbon remains unchanged.

endothelial NOS and neuronal NOS, by controlling electron transfer from the reductase domain to heme domain. Without this required process, the reaction does not take place, therefore, Ca^{2+} -CaM exerts complete control over the reaction. NO is toxic, and so it is absolutely crucial in NO signaling to strictly control the amount of NO that is made. Tight regulation over Ca^{2+} concentrations in the cell provides this required level of control. In general, nM concentrations of NO are synthesized by the generator cell, and pM concentrations act in the target cell. inducible NOS (iNOS) was first described as a Ca^{2+} -CaM-independent isoform, but subsequent studies showed that Ca^{2+} -CaM copurified with this isoform. It is, therefore, constitutively active. Because the function of iNOS is in the host response to infection, a NOS isoform that is constitutively

active and produced at the site of infection conforms to this biological role.

A number of inhibitors of NOS have been developed. The initial molecules were simple derivatives of the substrate L-arginine; however, other nonarginine-related structures were later found that were derived largely from library screens in the pharmaceutical industry, and some demonstrate significant isoform selectivity.

Chemistry of NO

NO is unstable in aqueous, aerobic solution. The stable end products of NO decomposition are nitrite (NO_2^-) and nitrate

Figure 3 Relevant solution chemistry of nitric oxide. NO reacts with O_2 in aqueous solution to produce nitrogen dioxide ($\bullet\text{NO}_2$) (eqn [1]). $\bullet\text{NO}_2$ then reacts with another molecule of $\bullet\text{NO}$ to produce dinitrogen trioxide (N_2O_3) (eqn [2]). N_2O_3 can then hydrolyze to yield NO_2^- (eqn [3]) or react with protein or low-molecular-weight thiols to make the S-nitroso derivative (eqn [4]). The S-nitrosated protein or small molecule is capable of homolytically cleaving to generate the thiol radical and $\bullet\text{NO}$ (eqn [5]).

(NO_2^-). The reaction sequence that leads to these products is shown in **Figure 3**. This solution chemistry consumes NO as it traverses a path from the generator cell to the target cell, hence the amount that arrives at the target cell is always lower. An intermediate along the reaction pathway is dinitrogen trioxide (N_2O_3). N_2O_3 can react with water as shown to produce NO_2^- or react with other cellular nucleophiles. The reaction with cysteine residues in proteins or with small cellular sulfur nucleophiles such as glutathione leads to the formation of S-nitrosated species as shown in **Figure 3**. S-nitrosated proteins and small molecules are known to decompose to the sulfur radical and NO in a so-called homolytic cleavage (**Figure 3**); certain biological conditions can accelerate the reaction. The significance of this chemistry is discussed below. NO has 11 valence electrons and, therefore, has one unpaired electron. The radical nature of NO dictates other chemistry, such as the facile reaction of NO with superoxide to give peroxynitrite ($^-\text{OONO}$), which then converts very quickly to NO_3^- , and the reaction with oxyhemoglobin to give methemoglobin and NO_3^- , again with the intermediacy of $^-\text{OONO}$. Peroxynitrite is a potent oxidant and has been shown to be important in various types of tissue damage associated with the formation of high levels of NO. The decomposition of relatively high concentrations of NO in tissue that occurs under inflammatory conditions leads to nitration chemistry, most frequently seen on tyrosine residues.

Guanylate Cyclase

The soluble isoform of sGC is the receptor for NO in target cells. Activation of sGC leads to the formation of cGMP, and then through a cascade involving cGMP-dependent kinases, a lowering of intracellular Ca^{2+} occurs, leading to effects such as smooth muscle relaxation (e.g., vasodilation). sGC is a heterodimeric protein composed of two subunits. The best characterized is the physiologically occurring $\alpha 1\beta 1$ heterodimer, first isolated from lung tissue. The β -subunit contains a unique

ferrous heme cofactor that is the receptor for NO. This porphyrin, despite having the same ligation as the globins, does not bind oxygen; rendering it ideally suited to bind NO is the presence of a high-competing concentration of oxygen. Upon binding of NO, sGC is activated 300-fold over the basal activity, and a burst of cGMP is produced. cGMP then acts through cGMP-dependent kinases to bring about physiological responses such as vasodilation and other smooth muscle relaxation responses.

Tools to manipulate sGC are emerging and include 1H-[1,2,4]oxadiazole[4,3-a]quinoxalin-1-one (ODQ), which inhibits sGC by oxidation of ferrous porphyrin to the ferric oxidation, and a family of activators based on the structure of YC-1 (3-(5'-hydroxymethyl-2'-furyl)-1-benzyl indazole). This compound is a weak activator of sGC; however, YC-1 and CO activate sGC to the same level as NO, and YC-1 acts synergistically with NO. A class of activators based on the YC-1 structure that directly activate and are more potent than YC-1 are entering clinical trials.

Non-cGMP NO-Signaling Pathways

As mentioned previously, N_2O_3 is an intermediate that forms during the aerobic solution decomposition of NO. N_2O_3 is a potent nitrosating agent that reacts with the ω -amino group of lysine and the thiol of cysteine. Formation of S-nitrosated cysteines in proteins can cause a change in the biological activity of the protein. Although increasing studies are directed toward understanding the chemistry and biological activity of the S-NO bond and the formation of these bonds with small molecule thiols and protein thiols, critical aspects remain to be determined. For example, the formation of R-S-NO could occur via the solution reaction of N_2O_3 with the thiol or by an enzyme-catalyzed process. The former path would appear to be too inefficient, and an enzyme to catalyze the latter path has not been isolated. Other hypotheses advanced involve the reversible formation of R-S-NO, where again the R group could be either a low-molecular-weight species or a protein similar to phosphoryl transfer. The kinase and phosphatase equivalents are yet to be isolated. Confounding all these hypotheses is the chemical reaction of R-SH with N_2O_3 , which would be facilitated much beyond what would be expected to occur when nonbiological concentrations of NO are used.

There is another important outcome from the formation of S-nitrosated proteins and low molecular weight compounds like glutathione. The S-nitroso bond is known to homolytically fragment, forming NO and a thiyl radical. The NO so derived can then function to activate sGC as described above. This mode of generating NO is attractive in that it represents a semi-stable form of this signaling agent and could be a way to store, transport, and deliver NO. There is no question that the decomposition of NO in aerobic aqueous solution will lead to S-nitrosation; rather, the issue is whether the amounts formed *in vivo* are physiologically significant.

Glossary

Calnexin/calreticulin Endoplasmic reticulum (ER)-resident molecular chaperones/lectins that specifically bind to monoglucosylated *N*-glycans.

Cargo receptors Receptors for cargo proteins concentrated in budding vesicles. ERGIC-53, for example, is believed to be a cargo receptor for certain glycoproteins.

EDEM A protein that has a homology with ER α -mannosidase I, which is involved in glycoprotein-specific ER-associated degradation (ERAD). Recent studies have suggested that EDEM protein indeed retains α -mannosidase activity, which appears to act preferably on the C-arm of α 1,2-linked mannose.

ER-associated degradation (ERAD) If proteins newly synthesized in the ER cannot fold properly, such misfolded proteins are retrotranslocated from the ER into the cytosol, and finally they will be degraded by the proteasome in the cytosol. This process is well conserved from yeast to humans.

ER quality-control compartment (ERQC) An ER-derived compartment, which could segregate misfolded proteins in a microtubule-dependent fashion, thereby preventing them from interfering with ER functions. Some glycosidases (e.g., ER α -mannosidase I) or lectins (e.g., calnexin/calreticulin) are reported to be concentrated in the ERQC.

Malectin ER-resident lectins found in mammalian cells, it has a unique carbohydrate-binding specificity towards diglucosylated *N*-glycans.

OS-9/XTP3-B Putative degradation lectins involved in the recognition of misfolded glycoproteins in the ER. They are homologs of yeast protein, Yos9, and contain a mannose 6-phosphate receptor homology (MRH) domain.

UGGT A glucosyltransferase situated in the lumen of the ER. It only acts on glycoprotein substrates that are particularly unfolded, thereby serving as a 'folding sensor' in the ER quality-control system.

The early processing of *N*-glycans, occurring in the endoplasmic reticulum (ER) and early Golgi, is a relatively conserved event among eukaryotes. In mammalian cells, multiple α -glucosidases/ α -mannosidases are involved in this process. Recent evidence also suggests that these processes determine the fate of carrier proteins that go through the secretory pathway. In such a 'glycan-dependent' protein quality-control system, the subtle difference of structures can be dictated by carbohydrate-binding proteins (lectins) to regulate their folding, secretion, and/or degradation.

α -Glucosidases

Eukaryotic cells synthesize *N*-linked glycans by so-called '*en bloc*' transfer of, in most cases, the Glc₃Man₉GlcNAc₂ oligosaccharides (Figure 1) built on dolichol pyrophosphate onto the Asn-Xaa-Ser/Thr site (where Xaa can be any amino acid except Pro) of the nascent polypeptide in the ER lumen by oligosaccharyl transferases (OSTs).

After the transfer of glycans onto proteins, the first glycan-processing event that occurs is the trimming of the glucoses by ER α -glucosidases (Figure 2).

α -Glucosidase I is a type II membrane protein that removes the outermost α 1,2-linked glucose residue from a glycoprotein (residue a in Figure 1). A defect in the α -glucosidase I gene in humans, named congenital disorder of glycosylation (CDG) type IIb, has been reported in a neonate with various severe phenotypes, indicating that the removal of the terminal glucose is essential for proper human development.

α -Glucosidase II, on the other hand, is a soluble luminal enzyme acting on the inner α 1,3-linked glucoses (residues b

and c in Figure 1). This enzyme is composed of two subunits, α and β ; while the α subunit contains a catalytic activity, the β chain contains a C-terminal KDEL (Lys-Asp-Glu-Leu), which serves as an ER-retrieval signal, as well as a putative lectin domain (MRH domain; mannose-6-phosphate receptor homolog domain). Both subunits are essential for the full functionality of this enzyme.

Glucosidase inhibitors, such as castanospermine or 1-deoxynojirimycin, are often used to inhibit α -glucosidases I/II, while bromoconduritol is used as a selective inhibitor for α -glucosidase II.

Endo α -Mannosidase

Endo α -mannosidase is an enzyme present in the ER–Golgi intermediate compartment (ERGIC) and in the Golgi. The enzyme can convert Glc_{1–3}Man₉GlcNAc₂ to Man₈GlcNAc₂ (Figure 2), and therefore provides a backup processing pathway that can bypass the need for ER α -glucosidases I/II. This enzyme appeared relatively late in evolution and its occurrence is restricted to the chordate phylum, suggesting that this bypass route emerges to ensure the conversion of the high-mannose type to complex-type glycans in these animals.

Processing α -Mannosidases

After deglucosylation by ER α -glucosidases I/II, the next step in *N*-linked glycan processing involves the removal of four α 1,2-linked mannosidases to give rise to Man₅GlcNAc₂ (Figure 2). Processing α -mannosidases have been classified

EDEM, the third class of class I α -mannosidases

A protein called 'EDEM' (ER degradation enhancing α -mannosidase-like protein) is the third member of class I α -mannosidases. The Htm1/Mnl1 protein (an EDEM homolog) in yeast as well as EDEM proteins (EDEM1–3) in mammalian cells appear to be luminal, soluble proteins in the ER, except that the topology of EDEM1 protein is still controversial as it has been initially described as a type II transmembrane protein in COS cells. These results could be explained by variations in signal peptide cleavage in different cell lines. EDEM1 (but not the Htm1/Mnl1 protein in yeast) was originally discovered as an unfolded protein response (UPR)-inducible gene, implying its role in tolerance against ER stress. EDEM2/3 are subsequently identified by a sequence homology search with EDEM1, and their involvement in ER-associated degradation process has been assessed. Now, expression of all EDEM proteins is shown to be induced upon activation of the ER stress pathway.

With respect to the enzyme activity of EDEM proteins, several lines of evidence suggest the presence of α 1,2-mannosidase activity, which prefers the cleavage of branch C (residue i in Figure 1) in EDEM1/3 proteins as well as in Htm1/Mnl1, despite the lack of evidence for enzyme activity in purified proteins. The demannosylation of the C branch by EDEM proteins is suggested to play an important role in glycan-dependent ER-associated degradation machinery, as the exposed mannose residue appears to be recognized by degradation lectins, OS-9 and/or XTP-3B protein (see later).

Class II α -Mannosidases Involved in N-Linked Glycan Processing

Golgi α -mannosidases II

After the formation of the $\text{Man}_5\text{GlcNAc}_2$ structure by Golgi α -mannosidases I, a single GlcNAc residue is added by the action of uridine diphosphate-*N*-acetyl glucosamine (UDP-GlcNAc): α -3-D-mannoside β -1,2-*N*-acetylglucosaminyltransferase I (GnTI) (Figure 2). The $\text{GlcNAcMan}_5\text{GlcNAc}_2$ glycan is further demannosylated by class II Golgi α -mannosidases and Golgi α -mannosidase II/IIx (Man2A1 and Man2A2, respectively). Golgi α -mannosidase II is a type II membrane protein and does not require cations for enzyme activity. It was previously shown that Golgi α -mannosidase II physically associates with GnTI, suggesting that the protein–protein interaction plays a role in its Golgi localization. Mice lacking the *MAN2A1* gene develop a dyserythropoietic anemia concurrent with loss of erythrocyte complex-type *N*-glycans. This phenotype resembles human congenital dyserythropoietic anemia type II (HEMPAS, hereditary erythroblastic multinuclearity with a positive acidified-serum lysis test).

It was surprising that, in *MAN2A1*-null mice, some none-rythroid cells still produced complex-type *N*-glycans, suggesting the occurrence of an alternative processing pathway. The gene encoding α -mannosidase IIx (Man2A2) was found in the human genomic library by cross-hybridization using a complementary DNA (cDNA) for *MAN2A1* as a probe. This enzyme also is a type II membrane protein. Targeted disruption of *MAN2A2* in mice resulted in male infertility. This phenotype is believed to be due to the absence in the testis of a GlcNAc-terminated complex-type *N*-glycan required for adhesion between germ cells and Sertoli cells.

Recently, it has shown that both Golgi α -mannosidase II and IIx require prior action of GnTI. The double knockout (KO) mice of these enzymes were found to have much more severe phenotypes, that is, perinatal death, than either single KO mice. Structural analysis of glycans revealed that the double KO mice completely lack complex type *N*-glycans, implying that Golgi α -mannosidase IIx can serve as the sole alternative enzyme for Golgi α -mannosidase II.

Recognition Molecules (Lectins) for Distinct Glycan Structures

It has been shown that the processing of *N*-linked glycans can determine the fate of secretory glycoproteins in the eukaryotes. To achieve this purpose, there are many luminal lectins with different specificities in the ER/ER–Golgi intermediate compartments (Table 1).

Cells utilize *N*-glycans as a 'tag' to be recognized by various different lectins, which could result in several distinct consequences for the substrate glycoproteins, that is, retention in the ER, promotion of folding, exit from the ER for vesicular transport, or degradation. Therefore, the proper processing of

N-linked glycans in the early secretory pathway by glycosidases is very critical for the quality control machinery of the secretory proteins.

Concluding Remarks

The N-linked glycan is one of the most conserved, commonly used modifications for secretory proteins. Therefore, it may not be surprising that the eukaryotic cells have evolved a highly sophisticated, N-glycan-dependent recognition system where the conditions of carrier proteins (e.g., folded vs. misfolded) are dictated by a subtle difference in glycan structure. In this regard, 'processing glycosidases' actually do more than processing, that is, creating signals for glycan-recognition systems. Complete understanding of this glycan-dependent quality control system still requires in-depth characterization of players, not only the glycosidases but also the lectins/glycosyltransferases involved in this process.

Glossary

Helicase An enzyme that utilizes nucleoside 5'-triphosphates to separate the two strands of the DNA double helix in order to form the single-stranded DNA (ssDNA) intermediates that are required for DNA metabolism (i.e., replication, recombination, and repair).

Processivity A measure of the average number of base pairs that can be unwound by a helicase before it dissociates from the DNA.

Translocase An enzyme that moves with either a 3'–5' or 5'–3' directionality along ssDNA using adenosine triphosphate (ATP) hydrolysis.

Functions

Helicases were originally identified as proteins capable of separating duplex DNA during replication, but have since been shown to function in a plethora of cellular responses, including displacement of proteins from DNA and RNA, chromatin remodeling, resolving Holliday junctions during recombination, and other nucleic acid conformational alterations. Unidirectional movement along single-stranded DNA (ssDNA) is central to the activity of SF1 helicases. For many SF1 enzymes, DNA unwinding and ssDNA translocation are separable activities due to their mechanism of action: a monomeric form of the enzyme is able to translocate along ssDNA, whereas an oligomeric form or multiple enzyme molecules are needed to observe DNA helicase activity.

The *Escherichia coli* Rep helicase is involved in replication, most likely playing a role in replication restart. Rep was first identified as being required for replication of bacteriophage ϕ X174. Rep in complex with the phage ϕ X174 gene A protein is highly processive, being able to unwind the entire genome (>6000 bp). However, in the absence of this accessory protein, Rep unwinds DNA with significantly lower processivity. *E. coli* UvrD, also known as helicase II, is involved in nucleotide excision repair and methyl-directed mismatch repair of DNA, as well as in plasmid replication. In the absence of accessory proteins, the unwinding processivity of UvrD is also relatively low. However, UvrD must be able to unwind at least 1000 bp processively during methyl-directed mismatch repair. The *Bacillus stearothermophilus* PcrA helicase is structurally similar to UvrD and Rep, and functions in DNA replication in complex with the replication initiator protein RepD which enhances its processivity and DNA unwinding activity. Therefore, the processivity of each of these helicases can be increased through interactions with accessory proteins.

Most DNA helicases show a preference for unwinding duplex DNA possessing an ssDNA flanking region or tail *in vitro*, and generally display a defined directionality of unwinding with respect to the backbone polarity of the ssDNA tail that flanks the duplex DNA. Helicases that initiate unwinding more efficiently on DNA substrates with a 3'-ssDNA tail are referred to as '3'–5' helicases', whereas those that prefer DNA substrates possessing a 5'-ssDNA tail are referred to as '5'–3' helicases'.

The *E. coli* Rep, UvrD, and *B. stearothermophilus* PcrA helicases are 3'–5' helicases, whereas the phage T4 Dda protein is a 5'–3' helicase. The *E. coli* RecBCD helicase is a unique bipolar helicase possessing two SF1 helicase subunits which move with opposite directionalities along ssDNA, with RecB translocating 3'–5' and RecD translocating 5'–3'. These two motors move in the same net direction since each moves on one of the two complementary strands of the DNA double helix. It has now been demonstrated that monomers of each of these enzymes contain all that is necessary for unidirectional translocation along ssDNA, although the mechanistic basis for what governs directionality is not known. At high-protein concentrations, *E. coli* UvrD can also initiate DNA unwinding at a nick *in vitro*, which is the biologically important site for initiation of unwinding in its roles in methyl-directed mismatch repair and excision repair.

Helicases are allosteric enzymes, many of which function as oligomeric assemblies. The class of hexameric DNA helicases exemplifies such oligomerization. The general importance of oligomerization for the function of SF1 helicases is less clear and is the subject of current study. Although there is evidence that a monomer of the phage T4 Dda helicase, an SF1 helicase, displays limited helicase activity *in vitro*, monomers of Rep UvrD and PcrA do not display helicase activity *in vitro*, but must oligomerize in order to unwind DNA *in vitro*. The role of this oligomerization may be to activate the enzyme and to provide the functional enzyme with multiple DNA-binding sites that are important for increasing the processivity of DNA unwinding.

Structural Features of SF1 DNA Helicases

Primary Structures

Helicases have been classified into six families and superfamilies (SF1–SFVI) based on conserved amino acid sequence patterns. The SF1 and SFII helicases function as monomers or dimers, whereas the SFIII–SFVI members are predominantly hexamers. The SF1 superfamily (containing Rep, UvrD, and PcrA) is defined by seven conserved regions of primary structure, referred to as 'helicase motifs'. The only regions of sequence similarity that are shared uniformly among all of the helicase families are

motifs I and II, which correspond to the Walker A and B boxes that form part of the nucleoside-5'-triphosphate-binding site. The presence of these two motifs is necessary but not sufficient for a protein to have helicase activity. The remaining conserved regions of the SF1 helicases are involved in binding of nucleoside-5'-triphosphate and/or DNA.

Crystal Structures of SF1 Helicases

Crystal structures are available for several SF1 DNA helicases, including *B. stearotherophilus* PcrA, *E. coli* Rep, and *E. coli* UvrD (Figure 1). The apo form of PcrA as well as in complex with adenosine diphosphate (ADP) was solved at 2.5 and 2.9 Å resolution, respectively. Structures of *E. coli* Rep bound to ssDNA and in complex with ssDNA and ADP were solved at 3.0 and 3.2 Å, respectively. Structures of UvrD in complex with a 3'-ss-dsDNA junction, and in the presence of ADP-MgF₃ or the nonhydrolyzable adenosine triphosphate (ATP) analog, AMPPNP, were solved at 3.0, 2.2, and 2.6 Å, respectively.

The Rep (673 amino acids), PcrA (675 amino acids), and UvrD (720 amino acids) proteins are structurally similar and are shown schematically in Figure 1. These SF1 proteins consist of two domains (1 and 2), separated by a cleft; domains 1 and 2 are further composed of subdomains 1A, 2A, 1B, and 2B (Figures 1 and 2). Subdomains 1A and 2A are composed of central β -sheets flanked by α -helical regions and are homologous to each other as well as to the nucleoside-5'-triphosphate-binding domain of the *E. coli* RecA protein. Subdomains 1A and 2A both contain large insertions which form the α -helical 1B and 2B domains.

Crystal structures of *E. coli* Rep, UvrD, and *B. stearotherophilus* PcrA in conjunction with mutagenesis studies on several helicases indicate that amino acid residues in the seven conserved SF1 helicase motifs, I–VI and IA are involved in either nucleotide and/or DNA binding. As shown in Figure 2, motifs I, IA, II, and III are contained within domain 1A, motifs V and VI are contained within domain 2A, whereas domain IV is found at the cleft formed between domains 1A and 2A. In general, ADP interacts with residues in motifs I and IV, whereas ATP interacts with residues within or near all of the motifs, with the apparent exception of motif IA.

In the crystal structures, ssDNA is bound with a defined orientation with respect to the polarity of the sugar-phosphate

backbone and the 3'–5' direction runs from domain 1 to domain 2 across the cleft between the two domains, with the 3' end of the ssDNA located in a groove formed between subdomains 1A and 1B. Several of the helicase motifs appear to be involved in the transmission of information between the ATP and ssDNA-binding sites within a monomer. Motif V residues are also likely to be involved in both ssDNA binding as well as ATP binding through interactions with the γ -phosphate. Motif VI interacts directly with the γ -phosphate of ATP, as well as with motif IV. The above summary considers only interactions that occur within a single monomer or subunit. However, since oligomerization of Rep, UvrD, and PcrA is functionally important for helicase activity *in vitro*, important allosteric interactions also might occur between two monomers.

Open and Closed Conformations

The asymmetric unit of the Rep-ssDNA crystal structure shows two molecules of Rep bound to a single molecule of dT(pT)₁₅. The conformations of the two Rep monomers are strikingly different with respect to the orientation of the 2B subdomain relative to the other three subdomains (Figures 1(a) and 1(b)). These two conformations, referred to as closed and open, respectively, differ by a 130° rotation of the 2B subdomain about a hinge region connecting it to the 2A subdomain. It has been speculated that the 2B subdomain might be part of the interface between subunits within the Rep dimer. The essential nature of the 2B subdomain in Rep was tested by making a *rep* gene construct in which the coding region for the entire 2B domain was deleted and replaced by three glycines. The resulting Rep Δ 2B protein retains helicase activity *in vitro* and can also support ϕ X174 phage replication *in vivo*, thus ruling out models invoking an essential role for the 2B domain in the helicase activity of Rep. In fact, a monomer of the Rep Δ 2B protein displays limited helicase activity *in vitro* in stark contrast to a wild-type Rep monomer which displays no helicase activity *in vitro*. This indicates that individual Rep monomers do possess all that is needed to unwind duplex DNA. However, the 2B subdomain appears to inhibit the helicase activity of the monomer and, thus, may have a regulatory function. This inhibition is relieved upon formation of a Rep or UvrD dimer. In the crystal structures of UvrD and PcrA

Figure 1 Structure of SF1 helicases bound to DNA. Subdomains 1A (orange), 1B (blue), 2A (red), and 2B (green) are indicated. In all the structures, the 3' end of the ssDNA resides near domain 1. In the two Rep structures, the open and closed conformations of the 2B domain and their position relative to the ssDNA are depicted.

Structural domains:

Helicase motifs:

Figure 2 The domain structure of *E. coli* Rep monomer. The positions of the subdomains and the helicase motifs within the primary structure of Rep are also shown. The color scheme for the individual motifs corresponds to that shown in Figure 1. Modified from Korolev S, Hsieh J, Gauss GH, Lohman TM, and Waksman G (1997) Major domain swiveling revealed by the crystal structures of complexes of *E. coli* Rep helicase bound to single-stranded DNA and ADP. *Cell* 90: 635–647.

monomers bound to duplex DNA with a 3' ssDNA tail, residues in the 2B subdomain make contact with the duplex DNA and it has been inferred that these contacts are important for helicase activity; however, since PcrA, Rep, and UvrD monomers are unable to unwind DNA, the exact role of this interaction is not clear. Recently, UvrD and PcrA monomers have been shown to bind with specificity to ss–dsDNA junctions possessing a 5' ssDNA tail and to initiate translocation from the junction. Furthermore, mutations in the 2B subdomain affect this junction specificity. Hence, the 2B subdomain duplex DNA interaction may function to load the monomeric forms of these enzymes at ss–dsDNA junctions so that they can use their ssDNA translocation activity rather than their helicase activity.

ssDNA Translocation by Monomers of SF1 Helicases

Monomers of PcrA, Rep, and UvrD are able to translocate with biased directionality (3'–5') along ssDNA in an ATP-dependent reaction. During translocation, these monomeric enzymes hydrolyze one ATP per DNA base translocated. However, since monomers of Rep, UvrD, and PcrA are unable to unwind duplex DNA *in vitro*, it is clear that ssDNA translocation alone is insufficient for DNA helicase activity for these helicases, and that dimerization is required. By contrast, the

phage T4 Dda enzyme has the ability to unwind DNA as a monomer but its unwinding processivity is enhanced when multiple monomers operate on the DNA.

DNA Unwinding by SF1 Helicases

Protein Oligomerization Is Required for Helicase Activity *In Vitro*

Single-turnover DNA-unwinding studies indicate that Rep monomers are unable to unwind DNA *in vitro* and that Rep oligomerization is required for initiation of DNA helicase activity *in vitro*. Single-molecule fluorescence techniques have shown that a monomer of Rep uses ATP hydrolysis to translocate toward the ss–dsDNA junction, but then displays futile ATP-dependent conformational fluctuations, followed by dissociation of the monomer. DNA unwinding is initiated only if a functional oligomeric helicase is formed. Significantly, partial dissociation of the oligomeric helicase during unwinding leaves an inactive Rep monomer, resulting in a stalled complex. This stalled complex can be resolved in two ways. Dissociation of the remaining bound monomer leads to rewinding of the DNA duplex; however, re-initiation of unwinding can occur upon re-formation of the functional helicase by binding of additional Rep protein. These results show that a Rep monomer is unable to sustain DNA unwinding after the active Rep oligomeric complex disassembles. This also suggests that the low unwinding processivity observed for Rep DNA unwinding *in vitro* may be due to the relative instability of the functional dimer.

Initiation of DNA unwinding *in vitro* also requires a dimeric UvrD complex in which one subunit is bound to the ss–dsDNA junction, while the second subunit is bound to the 3' ssDNA tail. Since the assay used in these UvrD studies relies on complete unwinding of an 18-base-pair (bp) duplex, these results cannot exclude the possibility that monomers might unwind a short stretch of DNA duplex; however, processive unwinding of an 18-bp duplex requires UvrD oligomerization. Therefore, simple unidirectional translocation of a UvrD, Rep, or PcrA monomer along ssDNA is not sufficient for helicase activity.

Mechanisms for DNA Unwinding and Translocation by SF1 Helicases

Whereas it seems likely that SF1 helicases share some features of their unwinding mechanisms, it is still too early to conclude whether a single mechanism applies to all SF1 helicases. In fact, there are clear differences among some of the SF1 helicases studied to date. Although Rep, UvrD, and PcrA must oligomerize to function as helicases *in vitro*, a monomer of the phage T4 Dda helicase possesses limited unwinding activity *in vitro*. It is therefore possible that some SF1 helicases function as monomers to unwind short stretches of duplex nucleic acids, while oligomerization may be necessary to activate some SF1 helicases or to enhance their processivity. Of course, interaction of a helicase with an accessory protein may also modify the need for the helicase to oligomerize by providing a second DNA-binding site. It is also likely that oligomerization serves as the means by which the translocation and helicase activities of Rep, PcrA, and UvrD can be separated. That is, monomers of

these enzymes may actually function as translocases rather than helicases and oligomerization is needed to turn them into active helicases.

Most proposed mechanisms for DNA unwinding and helicase translocation assume the functional helicase to possess at least two DNA-binding sites. Differences in current models for DNA unwinding center on three aspects: (1) whether translocation of the helicase along ssDNA is sufficient for helicase activity or whether the helicase also interacts directly with the duplex DNA; (2) whether the two DNA-binding sites are contained within a single polypeptide; and (3) whether the same DNA-binding site remains as the lead site (inch-worm model) or whether multiple sites alternate as the lead subunit (rolling or hand-over-hand model).

Inch-Worm Mechanisms for ssDNA Translocation by SF1 Monomers

Based on the crystal structures of PcrA bound to DNA, a PcrA monomer has been proposed to unwind DNA by an inch-worm mechanism (Figure 3). Yet, unwinding by PcrA, Rep, and UvrD monomers *in vitro* has not been observed. However, aspects of this model may explain the mechanism of directional translocation along ssDNA. In the structure, the 2A domain contacts the ds-ssDNA junction and the 1A domain is bound to the ssDNA region. The inch-worm model proposes conformational changes in the 1A and 2A domains coupled to ATP binding and hydrolysis enables processive movement of the monomer on DNA. In the absence of ATP, the 2A domain binds weakly to dsDNA whereas the 1A domain has a high affinity for ssDNA. Binding of ATP in the cleft between the two domains results in closure of the space between the two domains and is coupled to a switch in the DNA-binding affinities, that is, 2A binds tightly to DNA whereas 1A binds with weaker affinity. ATP hydrolysis reverses the DNA-binding affinities and results in a net movement of one base per ATP hydrolyzed.

Interestingly, a recent structure of the *Deinococcus radiodurans* RecD2, an SF1 translocase with 5'-3' directionality indicates that it binds to ssDNA with the orientation as do Rep, PcrA,

and UvrD, all of which are 3'-5' translocases. Therefore, the basis for the different directionalities of translocation is not due to a different binding orientation. Rather, it has been suggested that the protein conformational changes that drive translocation are simply reversed.

Active versus Passive Mechanisms of DNA Unwinding

One operational distinction among DNA unwinding models is whether the helicase participates directly in destabilizing the duplex DNA (active mechanism), or whether the helicase interacts solely with the ssDNA and waits for transient fluctuations in the duplex to form a ssDNA region (end fraying) onto which the helicase can then translocate (passive mechanism). Active mechanisms would generally involve direct binding of the helicase to the duplex DNA (or the duplex-ssDNA junction), in addition to the ssDNA, although a torsional mechanism is possible in which binding of the helicase to both single strands might unwind the duplex without direct duplex interactions.

Tests of a passive mechanism of unwinding have been made for *E. coli* Rep and UvrD helicases using non-natural DNA substrates in which a region of the ssDNA adjacent to the duplex was reversed in its backbone polarity or replaced by polyethylene glycol. The segments of polyethylene glycol or reversed polarity ssDNA would prevent a helicase from translocating up to the ss-dsDNA junction, thus a helicase operating by a passive mechanism would not be expected to unwind such DNA substrates. However, Rep and UvrD can unwind such DNA molecules, ruling out a passive mechanism for these helicases.

Dimeric, Subunit Switching Models

Active, Rolling or Hand-Over-Hand Models for a Dimeric Helicase

An active, rolling mechanism (Figure 4(a)) has been proposed for how a Rep dimer might unwind DNA and translocate along

Figure 3 Inch-worm mechanism of helicase/translocase movement on DNA. The two hands represent the 2A and 1A domains respectively. Reprinted from Soultanas P and Wigley DB (2000) DNA helicases: 'Inching forward'. *Current Opinion in Structural Biology* 10: 124–128, with permission from Elsevier.

Figure 4 Models for DNA unwinding and translocation by a dimeric helicase. (a) Active, rolling or hand-over-hand model, and (b) dimeric inch-worm model.

the DNA filament. In this model, the individual subunits alternate as the lead subunit, which binds to duplex DNA, followed by unwinding. However, all of the evidence upon which this model was based is also consistent with a dimeric inch-worm model shown schematically in [Figure 4\(b\)](#).

Dimeric Inch-Worm Models

The only difference between the rolling and dimeric inch-worm models is that the same subunit remains as the lead subunit in the dimeric inch-worm model. In fact, recent evidence with both Rep and UvrD favours a dimeric inch-worm model rather than a rolling or hand-over-hand model. Based on the fact that monomers of Rep and UvrD are able to translocate along ssDNA with biased (3'–5') directionality, it seems most likely that in a dimeric inch-worm model, the trailing subunit of the dimer might maintain continuous contact with the 3' ssDNA, possibly providing the motor component of the helicase, whereas the leading subunit would interact with the ss–dsDNA junction. However, such details are still speculative and need to be tested.

Protein Displacement by SF1 Translocases

Apart from their ability to translocate and unwind DNA, SF1 helicases also function in DNA repair by removing recombination factors from DNA. UvrD removes RecA from ssDNA and this activity is also conserved in its yeast (Srs2) and human (RTEL1) orthologs. Translocation on ssDNA is most likely required for this activity as it pertains to RecA/Rad51 nucleoprotein filaments formed on ssDNA. Apart from the motor activity of the translocase, specific protein–protein interactions are required for this displacement activity. The domains/residues that mediate such interactions are yet to be identified in UvrD or Rep. As mentioned above, the 2B domain is inhibitory to the DNA unwinding activity of Rep and it remains to be tested if this domain has a role in displacing other proteins from DNA. Since a monomer efficiently translocates on ssDNA, it might be the active form of the translocase during protein displacement, but a protein bound on DNA could serve as a potent blockade and the requirement for multiple translocases cannot be ruled out.

Summary

It is now clear that monomers of SF1 helicases are able to translocate along ssDNA with biased directionality in an ATP-dependent reaction. These monomers must use some sort of inch-worm mechanism for this translocation. However, monomers of Rep, UvrD, and PcrA are not able to initiate DNA unwinding *in vitro*, despite the fact that these monomers can translocate along ssDNA with directional bias. Therefore, the ability to translocate with unidirectional bias along ssDNA is not generally sufficient for a protein to have helicase activity. The 2B subdomain of Rep is not required for its helicase activity *in vitro*; in fact, this domain inhibits the ability of a Rep monomer to unwind DNA *in vitro*. Rep, UvrD, and PcrA require oligomerization in order to initiate DNA unwinding *in vitro*, thus the inhibition of helicase activity by the 2B subdomain of Rep appears to be relieved through oligomerization.

Glossary

Crystal structure High-resolution structural data derived from protein crystals.

Double-strand break Severe DNA damage where both strands of the helix break.

Micro-homology Short stretches of matching sequences in otherwise noncomplementary DNA strands used to promote break repair.

Nonhomologous end joining The repair of double-strand breaks without the use of a homologous DNA template.

Double-Strand Break Repair

DNA is exposed to a number of endogenous and exogenous agents, which can cause major structural damage. Double-strand breaks (DSBs) are the most lethal form of DNA damage as they prevent replication of the genetic 'blueprint' of life. Specific types of damaging agents, including ionizing radiation (IR) and reactive oxygen species (ROS), are capable of causing both strands of the DNA helix to be severed. All forms of cellular life maintain molecular pathways for repairing such dangerous lesions. The two major pathways are homologous recombination (HR) and nonhomologous end joining (NHEJ). HR requires an identical DNA donor copy of the broken molecule in order to accurately replicate the genetic information. NHEJ facilitates the direct joining together of broken DNA ends in the absence of a template. NHEJ can repair 'clean' breaks or remodel severely damaged termini to reconnect DNA ends. This process can be achieved by harnessing short regions of complementary bases, known as 'microhomologies', to form a connection between the ends, which is then cleaned up, if required, by polymerases and nucleases, prior to resealing by DNA ligases.

Different NHEJ Enzymes Are Required for Different Breaks

NHEJ is found in many organisms and typically the system is composed of a DNA end-binding protein (Ku), a ligase, a polymerase, and a nuclease. Ku recognizes DSBs and grasps the ends of the broken strands. Since DNA damage occurs in many different ways, the effects on the molecule can greatly differ. If the DNA duplex is neatly broken into two and the ends remain complementary, then the phosphate backbone can be rejoined directly by a specific ligase enzyme. Sometimes DSBs have single-stranded overhanging bases, which cannot be directly ligated (Figure 1). In this case, a nuclease activity removes or resects bases from the end until the two termini can be reconnected, often by microhomology. If there are any remaining gaps in the DNA, a specific NHEJ polymerase can fill them in, before the ligase finalizes the repair.

Cell-Cycle-Dependent DNA Break Repair

In eukaryotic cells, HR is the dominant DSB repair pathway in the S and G₂ phases of the cell cycle. HR is an error-free method

of replacing lost genetic material using the sister chromatid as a template. However, only a single copy of the genome is accessible during the nondividing stationary phase (G₁/G₀) of the cycle. If a break occurs in this phase, NHEJ is required to directly repair the DSB without relying on an intact template. For this reason, NHEJ can produce inaccurately repaired DNA, although the extent of the lost genetic information is thought to depend on the nature of the break. In eukaryotes, NHEJ often fails to replace lost nucleotides at the site of the DSB at either end. The ability of the NHEJ enzymes to remodel cleaved ends also inherently introduces variation to the site of repair, but this is preferable to cell death.

Bacterial NHEJ

For many years, the NHEJ repair pathway was thought to be exclusive to eukaryotes; however, in the last decade, it has been discovered in most species of bacteria and some archaea. Mammalian NHEJ requires five core components for NHEJ; DNA Ligase IV/XRCC4 complex, XLF, the heterodimer Ku70/80, DNA PK, and Artemis. By contrast, most bacterial NHEJ systems appear to require just two proteins: ligase D and Ku. In bacterial species such as *Mycobacteria tuberculosis* and *Pseudomonas aeruginosa*, ligase D (LigD) is a multifunctional enzyme, capable of various DNA remodeling and repair activities. These proteins are responsible for maintaining stability of the bacterial genome during stationary phase, which might encompass prolonged periods of nutrient starvation. Sporulating bacteria, such as *Bacillus subtilis*, also require NHEJ repair in the haploid spores. Both quiescent mycobacteria and *Bacillus* spores are not actively replicating, but are still accumulating significant prolonged DNA damage. HR is not a viable repair mechanism for this scenario; so, NHEJ is maintained as a practical solution to preserve an intact genome. Interestingly, not all bacterial species encode NHEJ proteins, and *Escherichia coli* is a notable example, but even these organisms appear to utilize a ligase-dependent process to repair DSBs in stationary phase.

Bacterial Ku

All Ku proteins form dimeric ring-like structures, capable of sliding over DNA ends. Ku does not bind to specific genetic sequences, nor make extensive contacts with the phosphate

Figure 1 Mechanism of NHEJ in prokaryotes. Ku homodimers bind to the ends of the DNA break and recruit LigD via the polymerase. The polymerase domain of LigD specifically binds to a 5' phosphate and, together with Ku, promotes end synopsis. The nuclease and polymerase activities of LigD, and possibly other factors, process the break termini, if required, to restore complementary ends. Finally, sealing of the nicks by ligase domain repairs the break.

backbone. Instead, Ku fits around the major and minor groove contours of the DNA, analogous to a nut on a bolt. Ku is thought to initially recognize and bind broken DNA termini and then recruit LigD for end processing, gap filling, and ligase activities. Although no crystal structure of bacterial Ku exists, deletion mutants have demonstrated that Ku binds to the polymerase domain of LigD, and greatly stimulates end joining *in vitro*. Bacterial Ku is usually found as a single gene and exists as homodimers. It is much smaller than the eukaryotic Ku proteins and does not include the vWA and SAP domains that make Ku 70/80 distinct. These additional domains allow eukaryotic Ku to behave as a scaffold protein and interact with the variety of factors in the more complex NHEJ system. The eukaryotic Ku70/80 heterodimer was likely the result of a gene duplication of a Ku homodimer at some point in evolutionary history and examples of such operon-encoded duplications exist in bacteria.

Bacterial DNA LigD

Ku and LigD represent a functional two-component NHEJ system in bacteria. Plasmid repair has been achieved *in vitro* utilizing just Ku and LigD, and deletions of both *in vivo* significantly reduce the frequency of NHEJ repair events. Deletion of

LigD in bacteria is nonlethal, unlike the essential LigA which is used during DNA replication. LigD is not necessary for survival under normal growth conditions; however, LigD null mutants (Δ LigD) in mycobacterium are sensitized to IR and have a lower survival rate than wild-type cells. In some bacteria, LigD operates as a compact multifunctional repair enzyme, with three distinct domains each with related catalytic activities; ligase, polymerase, and nuclease. The order of these three domains is not strictly conserved throughout different bacterial species and many LigDs possess only ligase and polymerase domains. It should also be noted that many prokaryotes encode these activities on distinct genes that are commonly operon associated.

The ligase domain of LigD is the largest of the three subunits and is used exclusively for the final nick-sealing step of NHEJ. Mutation of the catalytic residues in the ligase domain prevents successful NHEJ. The polymerase domain exhibits a remarkable versatility of nucleotide incorporation. Nucleotides can be added to blunt ends without template (terminal transferase), in gaps in the sequences, and opposite damaged bases. This NHEJ polymerase is not a member of the family X polymerases, like the human NHEJ polymerases μ , λ , β , and TdT. Instead, the bacterial polymerase is a member of the archaeo-eukaryotic primase superfamily. The implication of this discovery is that the NHEJ polymerase may have evolved into the end-joining role from a primase.

Several crystal structures of different bacterial NHEJ polymerases have been solved, including one bound to DNA. These structures have demonstrated key amino acid residues that contact the DNA in different places and those which guide the incoming nucleotide into the active site ready for addition. The crystal structure of a complete LigD has not been solved, although the isolated ligase domain has been elucidated. The structure of phosphoesterase/nuclease (PE) domain has also yet to be solved, which may hold the key to its specific role in NHEJ. The PE domain is capable of removing both nucleotides and phosphate groups from the ends of DNA, although loss of these activities does not affect NHEJ in plasmid repair assays; therefore, its exact role remains to be established. It is thought that an unidentified nuclease may provide nucleolytic activity in bacterial NHEJ.

Mechanism of Prokaryotic NHEJ

In the event of a DSB, Ku rapidly binds the broken ends, protecting them from exonucleolytic degradation. LigD is then recruited to the break by Ku via its polymerase domain. Recent crystallographic and biochemical studies have determined that two polymerases can work in concert to bring the DNA ends into direct contact, using specific surface loops to act as DNA end 'matchmakers' (Figure 1). This polymerase-mediated synopsis process utilizes microhomologies between the two ends to encourage base pairing. Depending on the nature of the damage to the DNA termini, bases may be removed by nucleolysis or added by the polymerase to promote end pairing by microhomology. Once the DNA strands are back in contact, polymerase and nuclease activities remove unpaired nucleotides and fill in the remaining gaps. Finally,

the continuity of the DNA is resorted by the ligase, which seals the remaining nicks.

NHEJ in Viral Infection

NHEJ is now known to be conserved throughout all forms of life, following its discovery in viruses. In 2006, mycobacteriophages were shown to possess functional Ku homologs. These viral proteins share the DNA-binding abilities and ring-like structure of the prokaryotic and eukaryotic orthologs. Following infection of *Mycobacterium smegmatis*, viral Ku proteins were shown to interact with the host LigD. The Ku proteins bind to the ends of the linear phage DNA and stimulate LigD to ligate the ends to produce a circularized genome, thus allowing rolling-circle DNA replication. Bacteriophage Mu encodes another Ku-like protein known as 'Gam'. Like the eukaryotic and bacterial homologs, Gam operates as a homodimer and binds to DNA. Gam is a much more distant relative of the Ku family and does not have a role in NHEJ repair but appears to protect the linear genome from degradation following injection into the host. It is plausible that this protective role of Ku-like proteins may be significant in enabling lateral gene transfer within bacteria, including phage genetic material. Ku may have initially existed as a phage protein, which became incorporated into bacteria and eventually evolved to participate in DNA break repair processes.

Roles for NHEJ in Bacteria

Many species of bacteria employ NHEJ to repair DSBs produced by exposure to IR; however, excessive exposure to IR is an unlikely environmental concern for prokaryotes. Homologs of Ku and LigD are present in a large variety of bacterial species; therefore, it is likely that these genes have been retained for a specific purpose. Bacterial survival of the extreme DNA-damaging effects of gamma irradiation coincides with improved survival of dehydration. Desiccation and dry heat are a more significant source of DSBs for bacteria. Preservation of a repair

pathway that can repair DNA breaks, produced under harsh environmental conditions, without the need for a DNA template is therefore highly beneficial. NHEJ provides this increased desiccation resistance which is seen in *M. smegmatis* and *B. subtilis* among others.

Mycobacterial infection of human hosts potentially requires a robust NHEJ system for survival, since any persistence is met with an immune defense. Mycobacterial cells subside into latent infection after the initial acute phase in human tuberculosis (TB). Macrophages cause oxidative damage to pathogens, capable of promoting DSBs in invading DNA as part of the immune response. Should Ku and LigD prove integral to the ability of *M. tuberculosis* to repair DSBs while in quiescence, development of inhibitors might have significant effects on the virulence of the bacteria.

Glossary

Apoptosis Also referred to as 'programmed cell death', an event that leads to loss of cellular morphology, loss of attachment, nuclear fragmentation, chromatin condensation, and chromosome fragmentation, ultimately resulting in cell death.

Cell-cycle arrest Cessation of cell division in response to cellular damage. Regulated by checkpoint proteins in the G1/S, intra-S, and G2/M stages of the cell cycle.

Hypomorphic mutation Mutation leading to reduction (but not annihilation) of the gene product's activity.

Ligation Formation of a phosphodiester bond between the 3' OH group of a DNA strand and the 5' PO₄ group of another DNA strand, linking both strands, catalyzed by a ligase.

Lymphocytes Type of white blood cells, divided into T-cells, B-cells, and natural killer (NK) cells. B-cells respond to pathogens by the secretion of antibodies (humoral immune system); T-cells mediate the release of cytokines and cytotoxins, which induce apoptosis of infected target cells (cellular immune system).

Cellular Responses to the Onset of DNA Double-Strand Breakage

The DNA helix is a vulnerable molecule. Chemical modifications of the DNA backbone and nucleotides are continuously introduced by both intra- and extracellular factors, despite the biological necessity for genetic integrity and robustness. Such modifying factors include oxygen radical species, reactive metabolites, and ionizing radiation, all of which have the capacity to modify the sugar-phosphate backbone of the DNA molecule in such a way that it breaks apart. When both strands of the helix are severed in close proximity, a DNA double-strand break (DSB) occurs. The presence of a DSB, in turn, can cause the chromosome to physically fall apart.

Chromosome breakage caused by the presence of a DSB leads to an uneven distribution of chromosomes over the daughter cells during mitosis, resulting in deletion or translocation of potentially critical genes, such as oncogenes or tumor suppressor genes. In order to prevent this, eukaryotic cells have developed different defense mechanisms, each working on a different level of the cellular organization. These mechanisms include cell-cycle arrest, the induction of apoptosis, and the actual repair of the DSB.

The uneven distribution of chromosome fragments during mitosis is primarily prevented by arrest of the cell cycle. Eukaryotic cells are equipped with checkpoints in the major phases of mitosis (G1, S, G2, and M), which are triggered by the presence of genomic breaks. Activation of a cell-cycle checkpoint introduces a delay in the mitotic progression during which the cell can repair its genomic damage through one or several of the available DNA repair pathways. Alternatively, a cell can initiate a process called 'apoptosis' or controlled cell death, which is believed to annihilate cells that are damaged to such an extent that adequate repair is unlikely.

Although these cellular responses to DNA breakage are mediated by an extensive cascade of proteins, one enzyme appears to play a particularly important role during the regulation of several of these processes: the ataxia telangiectasia

mutated (ATM) kinase. This serine/threonine protein kinase is activated shortly after the introduction of a DSB and is thought to be responsible for the phosphorylation of the nucleosome subunit H2AX – an important regulatory step during the initiation of cell-cycle arrest. In addition, ATM activates the cell-cycle-regulating protein Chk2 and the apoptosis-mediating protein p53. Finally, growing evidence suggests that the ATM kinase activity is important during actual DSB repair as well. In the light of this wide variety of regulatory functions, ATM is often referred to as a sensory protein.

Those cells that do not undergo apoptosis and are properly halted in their cell-cycle progression have two distinctly different pathways at their disposal for the proper repair of DSBs. A set of proteins and enzymes constituting the homologous recombination (HR) pathway mediates removal of a DNA fragment containing the break followed by resynthesis of the removed fragment. This process requires a homologous template to guide the DNA synthesis step and is therefore predominantly active during cycle phases in which sister chromosomes are present (S and G2). Contrarily, the nonhomologous end-joining (NHEJ) pathway is characterized by direct repair of the break which does not require a homologous template.

NHEJ: The Process and the Enzymes

In order to directly couple two pieces of DNA together without the need for template guided synthesis, it is necessary that the ends of the DNA fragments are first brought into close proximity. This initial step is followed by preparation of the DNA ends in such a manner that they become compatible for final ligation. The NHEJ process can, therefore, be roughly divided into an early phase, which consists of recognition and tethering of the DNA termini, and a later phase in which further processing and ligation take place. However, it should be noted that the core enzymes of the early phase interact with those of the later phase and that several subprocesses of tethering and processing

may actually overlap, causing the borders between the early and late phase to be less than clearly drawn.

It is generally accepted that the first factor to associate with both termini of the DNA fragments is a heterodimer consisting of an 86-kDa and a 73-kDa subunit – the Ku70/80 protein. Crystallography studies have revealed that the assembled Ku70/80 dimer assumes a ring-shaped structure which snugly fits the exposed DNA terminus. This unique structure–function relationship is responsible for the exceptionally high affinity of the Ku70/80 molecule for open DNA ends. The main body of the ring is composed of the central regions of the Ku70 and the Ku80 molecules, whereas the protruding carboxy-termini may be involved in stabilization of the Ku–DNA interaction or in regulation of other NHEJ factors.

The complex formed by the association of Ku70/80 with both DNA termini functions as the building basis for the entire NHEJ assembly. One of the factors attracted by Ku70/80 and generally associated with the early NHEJ phase is a 460-kDa serine/threonine kinase called ‘DNA-dependent protein kinase catalytic subunit’ (DNA-PK_{CS}). The kinase activity of DNA-PK_{CS} depends on binding of this enzyme to both Ku70/80 and the DNA termini. As such, DNA-PK_{CS} is truly the catalytic subunit of a greater assembly, consisting of the whole terminal DNA–Ku–DNA–PK_{CS} complex.

The DNA-PK_{CS} protein is considered a good candidate for the role of tethering factor – the core protein that mediates juxtaposition of the two DNA ends prior to processing and ligation. Both atomic force and electron microscopy studies have provided insight into the possible organization of the DNA–Ku–DNA–PK_{CS} complex, although these have not yet led to a definitive and unequivocal understanding of the positioning of the large DNA-PK_{CS} molecule at the DNA termini. The most likely predictions, however, are dimeric structures in which the DNA fragments are juxtaposed by two DNA-PK_{CS} molecules, each associated with its own Ku70/80 dimer and DNA terminus (see Figure 1). The existence of such structures is also suggested by a series of biochemical experiments.

The function of the DNA-PK_{CS} kinase activity during NHEJ is a matter of contemporary dispute. Deletion studies have shown that impairment of kinase domain results in diminished DSB repair, suggesting an important function. The quintessential substrate of the DNA-PK_{CS} kinase, however, is yet to be determined. In fact, it is likely that several NHEJ core factors are phosphorylated, activated, or regulated in some fashion by DNA-PK_{CS}.

One of the best-researched substrates for DNA-PK_{CS} is the DNA-PK_{CS} molecule itself. This protein possesses at least 16 autophosphorylation sites, which are serine or threonine residues located in three main areas of the protein’s structure: clustered around either amino-acid residue 2056 or 2609, or located in the carboxy-terminal catalytic domain. Convincing evidence exists that autophosphorylation of DNA-PK_{CS} alters the structural conformation of the DNA–Ku–DNA–PK_{CS} complex.

Although, at present, there are no details available on the specific function of each individual autophosphorylation site, it has become apparent that overall phosphorylation of the DNA-PK_{CS} molecule results in increased accessibility of the DNA ends to modifying enzymes such as nucleases and ligases. This finding has given rise to a model in which the large

Figure 1 Working model for nonhomologous end-joining. (a) Recognition of the DSB by Ku70/80. (b) Tethering of the DNA ends, followed by phosphorylation and autophosphorylation of DNA-PK_{CS}. (c) Processing of the DNA ends via different routes. (d) Ligation of the DSB.

DNA-PK_{CS} molecule functions as a gatekeeper – tethering the DNA ends and protecting them against improper degradation by sterically blocking access, until the two DNA termini have approached each other closely enough for DNA-PK_{CS} autophosphorylation to occur in trans (see Figure 1). This latter event renders the DNA ends available for further processing and subsequent ligation.

Recently, it has been suggested that autophosphorylation is not the only one responsible for the initiation of conformational changes in the DNA-PK_{CS} molecule. Phosphorylation of the 2609 and 2647 DNA-PK_{CS} residues may be mediated by another factor, the ATM kinase. ATM is quickly activated after the introduction of a DSB and is known to facilitate signal transduction events that play a role in the cell-cycle arrest events that accompany the repair of DNA breaks. It is now becoming clear that in addition to its function in signal transduction, ATM may appear at the stage of the actual NHEJ process as well. It is conceivable that ATM-mediated phosphorylation of certain DNA-PK_{CS} residues may be required in conjunction with DNA-PK_{CS} autophosphorylation in order to establish the proper set of conformational changes necessary for further modifications of the DNA ends. Such a double requirement for NHEJ progress may ensure proper alignment of the NHEJ process and related pathways such as cell-cycle arrest.

After the DNA termini are brought in close proximity and the tethering complex has assumed a configuration that allows access of other NHEJ factors, the DNA ends must be processed in order to yield a substrate for the final ligation step. To this end, the NHEJ process utilizes a set of enzymes, none of which can be considered to be specialized NHEJ factors; instead, they appear to be derived from the pool of generally available genome maintenance enzymes as needed. For instance, the addition of 5' phosphate groups as necessary for ligation is mediated by the multifunctional mammalian polynucleotide kinase and removal of 3' phosphoglycolates by a host of NHEJ-unrelated enzymes, including the endonuclease APE1 and the tyrosyl-DNA phosphodiesterase TDP1.

Generally, events that create DSBs do not leave a readily ligatable blunt-ended break. Commonly encountered structures will possess either 3' or 5' single-strand overhangs of variable length. The most elementary processing of such overhang structures is accomplished by either filling or resection (see [Figure 1](#)). Several factors have been reported to mediate the filling of overhangs during NHEJ by using the single-strand sequence as a template to synthesize the complete double-strand structure. Polymerases μ and λ are both thought to be recruited by the NHEJ process, although it is unclear how this recruitment is organized or regulated. Polymerase μ has been shown to interact with the Ku heterodimer, making it likely that the DNA–Ku scaffold is able to attract this processing enzyme to the repair complex. This mode of recruitments has also been observed for the human terminal deoxynucleotidyl-transferase (TdT) enzyme, which catalyzes the addition of nucleotides to DNA ends.

Knowledge of factors that mediate the resection of overhangs during NHEJ is presently limited to the Artemis nuclease. This enzyme was originally identified as a critical player during the process of V(D)J recombination, catalyzing the nucleolytic opening of hairpin structures. Because Artemis deficiency leads not only to impairment of V(D)J recombination, but also to radiation sensitivity, it was soon recognized that this nuclease may also be involved in the processing of DNA termini during NHEJ. The credibility of this notion is strengthened by the fact that Artemis is a substrate for phosphorylation by the two NHEJ kinases ATM and DNA-PK_{CS}, although the biological significance of this interaction is still far from obvious.

Artemis is known to physically associate with the DNA-PK_{CS} molecule. This association changes the catalytic activity of Artemis – residing in the amino-terminal region of the protein – from exonucleolytic to endonucleolytic and is, therefore, considered to be an important prerequisite for the processing function of Artemis during both NHEJ and V(D)J recombination. The Artemis nuclease is most likely recruited to the repair complex through its interaction with the DNA-PK_{CS} molecule, which, in turn, is anchored at the DNA break by association with the DNA–Ku complex. Recent evidence suggests that Artemis activity may be modulated through the carboxy-terminus of the Ku80 molecule, either by direct interaction or by alteration of DNA-PK_{CS} kinase or autophosphorylation activity. This intricate team play demonstrates once more the importance of the DNA–Ku complex as supporting scaffold for the entire NHEJ process.

After proper modification of the DNA ends, ligation will be mediated by a complex of two molecules: DNA ligase IV and

the X-ray cross-complementing group 4 (XRCC4). The amino-terminal region of ligase IV harbors its adenosine triphosphate (ATP)-utilizing catalytic domain and shares a marked homology with mammalian ligases I and II. The carboxy-terminus of ligase IV is very different from those of other mammalian ligases and contains two BRCT (BRCA1 carboxy-terminus like) motifs which possibly facilitate interaction of ligase IV with other proteins. Quite unexpectedly, however, the BRCT motifs do not govern the interaction of ligase IV's most prominent partner XRCC4. This is thought to be mediated by a stretch of approximately 30 nucleotides in between the two BRCT domains. The XRCC4 protein has a mushroom-shaped, dimeric structure consisting of a globular amino-terminal head and a long carboxy-terminal stalk. The crystal structure of the ligase IV/XRCC4 complex reveals a conformation in which two XRCC4 molecules are positioned side by side, while one ligase IV molecule associates with the extending carboxy-terminal stalks of the XRCC4 proteins.

Ample evidence suggests a direct interaction between the Ku70/80 heterodimer and the ligase IV/XRCC4 complex, possibly mediated by the BRCT motifs in the ligase IV molecule. This interaction markedly stimulates the ligase activity of the complex approximately by one order of magnitude. Therefore, specific recruitment and activation of the ligase IV/XRCC4 complex at a DNA break is most likely regulated by the DNA–Ku scaffold. The attachment of the ligase IV/XRCC4 complex to the NHEJ machinery may be further strengthened by binding of the amino-terminal heads of the XRCC4 molecules to the DNA helix.

It is at present not clear during which stage of the NHEJ process the ligase IV/XRCC4 complex joins the repair efforts. Classic models tend to include association of ligase IV/XRCC4 with the repair machinery as the last step before ligation. In the past years, however, these models have been disregarded as incomplete and evidence is accumulating that the ligase IV/XRCC4 complex may play an integral part in earlier phases of the NHEJ pathway. These functions notably include alternative processing of single-strand overhangs, in which ligase IV/XRCC4 and Ku cooperate to accomplish tethering of noncomplementary overhangs. Such intermediate structures can be converted into double-strand structures during an integrated processing/joining operation (see [Figure 1](#)). Possibly, this mode of alternative processing may circumvent the necessity to resect single-strand overhangs in a subset of repair events and may contribute to eliminate the loss of genetic information during NHEJ.

The notion that alternative processing routes may take place has considerably gained credibility after the recent discovery of a seventh NHEJ key protein: XRCC4-like factor (XLF), also known as Cernunnos. This relatively small protein bears a structural resemblance to the XRCC4 molecule and interacts with both Ku70/80 and ligase IV/XRCC4, stimulating ligation of noncompatible DNA ends. Quite possibly, XLF supports the alternative processing routes mediated by the interplay between Ku and ligase IV/XRCC4, thereby indirectly decreasing the total contribution of processing events that result in nucleotide loss. Resolution of the XLF crystal structure revealed that this protein is theoretically capable of associating with the ligase IV/XRCC4 complex in a 2:2:1 XRCC4:XLF:ligase IV ratio.

Accessory Proteins to the NHEJ Process

In addition to its key enzymatic machinery, the NHEJ process appears to utilize several proteins that are accessory to this pathway. For instance, the breast cancer type 1 susceptibility protein (BRCA1) is known to somehow stimulate NHEJ. Although the exact nature of BRCA1 involvement in NHEJ is unclear, several studies suggest that this protein is able to suppress DNA end processing, thereby reducing the loss of genetic information and increasing the fidelity of repair.

A complex of three proteins (MRE11, Rad50, and NBS1), known under the abbreviation MRN, plays a central role in the process of HR, but may also assist the NHEJ pathway in a subset of repair events. The Rad50 component of the MRN complex provides two extending, flexible arms that may be involved in tethering of DNA fragments. Although the NHEJ core enzymes provide a mechanism that supports DNA tethering, several authors have suggested that MRN may actually compete for available DNA termini throughout the repair process. Such interchangeability of factors between NHEJ and HR shades the borderline between these two pathways, but simultaneously provides insight into possible regulatory mechanisms that mediate the choice between DSB repair paths.

Function of NHEJ in V(D)J Recombination and Telomere Maintenance

The importance of the NHEJ pathway is not limited to the repair of accidentally introduced DSBs. Functionality of the NHEJ core enzymes is indispensable for two other major cellular processes: V(D)J recombination and telomere maintenance.

The process of V(D)J recombination takes place in developing T- and B-lymphocytes, where it is responsible for the rearrangement of immunoglobulin (Ig) or T-cell receptor (Tcr) gene segments. This generation of novel combinations accounts for the immune systems' vast potential to recognize a wide range of immunogenic threats, and is, therefore, of crucial importance for the development of both cellular and humoral immunity. New, active Ig or Tcr genes are created by the combination of three different types of gene segments: variable (V), diversity (D), and joining (J) segments. This requires the introduction of an incision at the edge of the segment and the subsequent religation of this segment with its selected partner through a process that is essentially identical to the repair of a DSB (see Figure 2).

The borders of the gene segments are marked by recombination signal sequences which are recognized by the two nucleolytic enzymes that mediate the incision: the RAG1 and RAG2 proteins (recombination-activating gene, RAG). The incision made by the RAG proteins typically leaves hairpin structures at the termini of the segments, which are called 'coding ends'. Before recombination and ligation of the gene segments can take place, these coding ends need to be opened by the Artemis–DNA-PK_{CS} dyad. Hairpin opening during V(D)J recombination requires activation of the Artemis endonuclease activity by association of this enzyme with the DNA-PK_{CS} kinase. Subsequent ligation of the cut and processed gene segments is carried out by the NHEJ core enzymes, which tether and join the DNA fragments as if repairing a DSB.

Figure 2 Working model for V(D)J recombination. (a) Creation of incisions at the recombination signal sequences by RAG1 and RAG2. (b) Processing of hairpin structures at the coding ends and ligation facilitated by the NHEJ core enzymes. (c, d) Completion of the V(D)J recombination process.

The involvement of the NHEJ core enzymes Ku70/80 and DNA-PK_{CS} in telomere maintenance is yet another testimonial for the general importance of this set of enzymes. Telomeres are defined as specialized structures at the ends of chromosomes which function to protect the chromosomes from degradation, recombination, or fusion. They consist of stretches of repeats of the TTAGGG sequence, which associate with telomere binding proteins and fold into a T-loop structure. Both Ku70/80 and DNA-PK_{CS} have been found to associate with the telomeres, most likely through direct binding of Ku to telomere repeat binding proteins. Disruption of this association by (null) mutation of the Ku or DNA-PK_{CS} proteins results in loss of telomere equilibrium. More specifically, the absence of Ku70/80 causes shortening of the telomeres, whereas the absence of DNA-PK_{CS} leads to elongation of the telomere sequence. Fusion of telomeres is observed after disruption of either Ku or DNA-PK_{CS}.

The mechanism by which these NHEJ factors mediate telomere protection is at present far from clear. The same can be said about the biological significance of telomere alteration, which is associated with such contrasting events as cellular senescence, aging processes, and tumorigenesis. The somewhat surprising involvement of NHEJ factors in the prevention of telomere joining events (theoretically the very opposite of the NHEJ core function: joining) will remain to be the target of intensive research for the immediate future.

NHEJ Enzymes in Human Diseases

Human diseases associated with NHEJ defects are invariably rare. Null mutations in most of the core NHEJ genes – with the notable exception of Artemis – are not observed in humans, indicating that the resulting phenotypical presentations may be too severe to be compatible with (human) life. Consequently, patients normally harbor only a hypomorphic mutation which allows for at least a residual activity of the affected factor. The few patients who were diagnosed with NHEJ defects generally suffer from a compromised immune system because corruption of the V(D)J process results in impairment of both cellular and humoral immunity; a condition that is often referred to as severe combined immune deficiency syndrome (SCID). When caused by mutations in NHEJ genes, the SCID condition is normally accompanied by increased sensitivity to ionizing radiation and is called radiosensitive SCID (RS-SCID).

At present, no patient with a Ku70 or Ku80 defect has been identified. The absence of a viable human phenotype may be indicative for the importance of the DNA–Ku scaffold during NHEJ and V(D)J recombination. Knock-out mouse models, however, are not embryonically lethal and display an RS-SCID phenotype, growth retardation, and a predisposition for the development of hematological malignancies. These presentations are in good agreement with the theoretical expectations for a human clinical phenotype should it ever be discovered.

Only one case of a hypomorphic DNA-PK_{CS}-defective RS-SCID patient has been documented so far. This patient presented with opportunistic oral and respiratory tract infections since the first months of life, which ultimately resulted in respiratory distress. The cause was determined to be a single missense mutation of the 3062 residue of DNA-PK_{CS}, thought to impair activation of Artemis and, consequently, the proper processing of coding end hairpins during V(D)J recombination. Patients that harbor mutations in the actual catalytic domain of DNA-PK_{CS} have as of yet not been reported.

Viable Artemis defects are relatively much more common and constitute the large majority of human RS-SCID cases. Both null- and hypomorphic mutations have been identified in human patients, all causing hypersensitivity to opportunistic infections, mainly of the respiratory tract. Null-mutations obliterate the maturation of B- and T-lymphocytes (T[−]B[−] SCID),

whereas hypomorphic mutations lead to profound but less severe lymphocytopenia. In addition, genomic instability and predisposition to the development of B-cell lymphomas are commonly associated with Artemis mutations. The existence of Artemis null-mutation patients suggests that the Artemis protein is not absolutely essential to life.

Hypomorphic mutation in the ligase IV gene results in LIG4 syndrome, which is characterized by immunodeficiency and often by microcephaly and growth retardation. The severity of these symptoms is reciprocally proportional to the residual ligase activity allowed by the mutation. A recent study has shown that reduction of ligase IV activity can result in prolonged processing of hairpin ends during V(D)J recombination, resulting in the loss of nucleotides around the joint which subsequently interferes with lymphocyte maturation. The phenotype of XLF patients resembles that of the LIG4 syndrome and is characterized by RS-SCID, dysmorphic features, growth retardation, and microcephaly.

Defects in the DSB signaling protein ATM give rise to the neurodegenerative disease ataxia telangiectasia (AT), which is characterized by the appearance of pronounced vasculature in the eye whites, loss of Purkinje cells in the cerebellum, and, consequently, marked impairment of motor skills. The aberrations that are at the basis of AT onset can be either hypomorphic or null mutations. The disease usually becomes apparent in the toddler years and is often, but not always, accompanied by increased sensitivity to ionizing radiation. Although ATM is not directly involved in NHEJ-mediated V(D)J recombination, AT patients often have a compromised immune system, the symptoms of which do not quite reach the severity of a SCID condition. Like most other NHEJ defects, AT is often accompanied by genomic instability and an increased incidence of hematologic malignancies. The neurological manifestations of the disease may be explained by non-NHEJ functions of the ATM protein, including its involvement in apoptosis and cell-cycle regulation (Table 1).

Inhibitors of the NHEJ Process and Radiation: Combination Therapies

Alleviation of the primary tumor burden is a common starting point for the treatment of most cancers, including metastasized

Table 1 The nonhomologous end-joining core factors

<i>NHEJ factor</i>	<i>Mol. weight^a</i>	<i>Discovery</i>	<i>Crystal structure</i>	<i>Primary interactions</i>	<i>Associated human disease</i>
Ku70	73	1981 ^b	Yes	Ku80	No patients known
Ku80	86	1981 ^b	Yes	Ku70	No patients known
DNA-K _{CS}	469	1990 ^c	No	Ku, Artemis	RS-SCID
Artemis		2001	No	Ku, DNA-PK _{CS}	RS-SCID, genomic instability, lymphomas
XRCC4	38	1990	Yes	Ligase IV, Ku	Single nucleotide polymorphism is associated with oral cancer
Ligase IV	96	1995	No	XRCC4	RS-SCID, LIG4 syndrome, growth retardation, genomic instability, leukemia
XLF	33	2006	Yes	Ku, XRCC4	RS-SCID, growth retardation, genomic instability
ATM	350	1995	No	P53, H2AX, Chk2, Nbs1	Ataxia telangiectasia

^aMolecular weights reflect literature consensus and are often based on measurements of apparent behavior.

^bOriginal discovery; Ku was not linked to DNA-PK_{CS} until 1990.

^cCoining of the name DNA-PK based on earlier observations (1985, 1988, 1990).

cancers which will require the additional inclusion of a chemotherapeutic regimen. Reduction of the primary tumor is commonly obtained either by surgical means or, more often, by radiation therapy. As modern radiology techniques have become precise enough to deliver a calibrated radiation dose within a specified spatial and temporal perimeter, researchers have been developing compounds that enhance the biological effects of the radiation exposure. Combining a systemic, subcytotoxic dose of a radio-sensitizing compound with strictly localized radiation delivery could theoretically result in a high-potential, tumor-specific therapy.

Because impairment of the NHEJ pathway increases sensitivity to ionizing radiation, current investigations are directed toward small-molecule inhibitors of NHEJ enzymes. At present, these inhibitors are mostly targeting the active sites of the ATM and DNA-PK_{CS} proteins. Because the kinase domains of ATM and DNA-PK_{CS} are structurally different from those of the main stream kinases, the cytotoxic characteristics of its inhibitors should be relatively mild in the absence of ionizing radiation.

Classical inhibitors of ATM and DNA-PK_{CS} include caffeine and wortmannin, a furanosteroid metabolite of a *Penicillium* fungus. However, the medicinal use of these natural compounds was found to be limited due to their low specificity and biological availability. A second generation of small molecular compounds was subsequently designed based on the structure of a compound called LY294002, which led to the development of the specific ATM inhibitor KU-55933 and the DNA-PK_{CS} inhibitor NU7441. At present, the feasibility of inclusion of these and other compounds in existing radiation protocols is being evaluated.

Glossary

DDE transposases Transposases in which the catalytic site includes two aspartate (D) and one glutamate (E) amino acid residues.

S transposases Transposases that resemble serine (S) site-specific recombinases.

Transposases Enzymes that catalyze transposition.

Y transposases Transposases that resemble tyrosine (Y) site-specific recombinases.

Y1 transposases Transposases that resemble rolling circle replicases and in which the catalytic site includes a single tyrosine (Y) amino acid residue. Member of the HUH protein family.

Y2 transposases Transposases that resemble rolling circle replicases and in which the catalytic site includes two tyrosine (Y) amino acid residues. Member of the HUH protein family.

Transposable elements (TEs) are small functional segments of DNA capable of translocation into DNA sites within and between genomes and play an important role in horizontal gene transfer. A major division between TEs is whether they translocate via RNA or DNA intermediates. Prokaryotic TEs are probably exclusively limited to those that move using DNA intermediates. They are capable of sequestering and transmitting a variety of genes involved in accessory cell functions, such as resistance to antimicrobial agents, catabolism of unusual compounds, and pathogenicity, virulence, or symbiotic functions. They also promote deletions and inversions and their insertion can activate or extinguish gene expression. TEs can constitute an important fraction of bacterial genomes (both chromosomes and plasmids). For example, one class of TE, bacterial insertion sequences, represents ~7% of the 4 Mbp *Bordetella pertussis* chromosome and ~40% of the 220 kbp *Shigella flexnerii* virulence plasmid pWR100.

Structural Similarities and Diversity

All TEs encode a cognate transposase (Tpase) or recombinase, which recognizes their ends and catalyzes the individual DNA cleavages and strand transfer, events necessary for transposition. In bacteria, the term 'transposon' (Tn) is limited to elements that carry genes specifying additional functions to those involved in transposition. A large number of TEs, which do not include a distinct phenotypic trait, are known as insertion sequences (ISs).

Definition of Transposases

Different types of elements can be defined by the nature of their cognate recombinases. In transposition reactions, these enzymes are known as 'transposases' (Tpases). The majority falls into a class generally called 'DDE transposases' because of the presence of three key amino acids, two aspartate residues and a glutamate, as part of the active site. Although DDE enzymes represent the majority of known Tpases, at least four

additional types of Tpase have been identified. One is similar to rolling circle replicase used by certain bacteriophages and plasmids. These are known as 'Y2 transposases' since their catalytic mechanism involves two highly conserved tyrosine residues. A second, the 'Y1 transposases', is related to the Y2 group but uses a single catalytic tyrosine. The other two are members of the site-specific recombinase families. However, while these Tpases show site specificity for the ends of the donor Tn, they appear more flexible than classic site-specific recombinases in the target DNA sequences they recognize and use. They are known as Y-Tpases and S-Tpases to distinguish them from tyrosine and serine recombinases.

Types of Transposable Elements

Insertion sequences

The smallest autonomous TEs known are the bacterial ISs and are present in almost all eubacterial and archaeal genomes. They are genetically compact (750–2500 bp), generally flanked by two partially identical and inverted sequences (terminal inverted repeats: IRs) and generally encode only functions involved in their mobility. The Tpase gene is composed of one or two open reading frames (*orfs*) occupying almost the entire length of the IS (**Figure 1(a)**). The IR proximal to the Tpase promoter is defined as IRL. In many ISs with two *orfs*, Tpase is produced as a fusion protein using a programmed –1 translational frameshift between the *orfs* similar to that observed in generating the pol polyprotein in some retro-viruses.

Our perception of ISs is gradually changing. While they were thought to encode only the Tpase gene, an increasing number are now being identified which include passenger genes such as transcription regulators, methyltransferases, and antibiotic resistance genes. These elements, simpler than known Tns, are called transporter ISs (tISs). Moreover, the number of IS91 family members has expanded enormously, and the Tpase has now been identified associated with a large number of antibiotic resistance genes in an extensive group of elements called IS with a common region (ISCR). The common region is the IS91-like Tpase. Thus, the dividing line between Tns and ISs is becoming less clear.

Figure 1 Diversity of bacterial transposable elements. The organization of different types of bacterial TE is shown. Terminal repeats (red triangles), transposon ends (red boxes in the case of IS91, IS605, IS607 and Tn916 to indicate that they are not inverted repeats), genes whose products are involved in transposition, site-specific integration or recombination (int, xis, R) functions (white boxed arrows), resistance genes, and accessory genes (conjugative transfer or phage functions) (blue boxes) are indicated. Gray boxes indicate recombination sites for resolution of cointegrates (*res*) or integron capture of gene cassettes (*att*). *bla*: resistance to β -lactams; *tet*: resistance to tetracycline; *mer*: mercury resistance.

Nearly 4000 bacterial ISs are known. These have been divided into 20–25 groups or families defined by their genetic organization, similarities in their IRs and Tnpase sequences, and their preference for given target DNA sequences. The majority of these families encode a DDE Tnpase. Another (IS91) encodes a Y2 enzyme, a third (IS607) encodes an S-Tnpase while a fourth (IS605/IS608) specifies a Y1 enzyme (Figure 1(a)). This classification will undoubtedly continue to evolve as more are characterized.

Miniature inverted repeat transposable elements

Several bacterial genomes harbor many copies of small DNA segments. Depending on the bacterial species, these are variously called *Rep*, *Box*, *Rup*, or *Correia*. Some, such as *Correia*, resemble ISs, which have been deleted for the Tnpase. While others, such as *Rep*, show structural similarities with members of quite a different family, IS200/IS605. Interestingly, the ends often resemble those of members of the IS630 family and like these elements are flanked by a directly repeated TA dinucleotide. These were first described in eukaryotic systems. Some of these derivatives also include passenger genes and are called MICs.

Compound transposons

Antibiotic resistance genes in bacteria are often flanked by a pair of similar IS elements. Flanking ISs can mobilize any

interstitial DNA segment. These structures are known as ‘compound transposons’. They are widespread and can include resistance to many different antibacterials, to genes involved in bacterial–host interactions as well as to other accessory genes, which are important to the host under some conditions of growth. Classical examples are tetracycline resistance Tn, Tn10 (flanked by two IS10 elements in inverse repeat) (Figure 1(b)), the neomycin resistance Tn, Tn5 (flanked by two IS50 elements in inverted repeat) and the chloramphenicol resistance Tn, Tn9 (flanked by two copies of IS1 in direct repeat). In some cases, the autonomy of the flanking ISs may be reduced in various ways to favor transposition of the entire structure.

Unit transposons

Another class of bacterial Tns are the unit Tns such as members of the Tn3 family (Figure 1(c)). Here, additional genes are contained within the transposable element itself. Large numbers of such Tns have been described carrying antibiotic resistance genes or genes involved in catabolism of unusual substances (including xenobiotics). Tn3-family transposons share very similar IRs (~40 bp) and carry highly related DDE Tnpase genes. They carry a specific site (*res*) and encode a site-specific recombinase (*tnpR*), which promotes recombination in the cointegrate between the two elements at their *res* sites. This leads to separation of donor and target molecules and

leaves a single copy of the Tn embedded in each. Many variations on this basic structure have been observed. They include derivatives, which encode only the T_pase with no additional genes and therefore might be included within the IS group.

Tn3-family elements can accommodate and accumulate additional genes. For example, Tn21 (Figure 1(c)) evolved by insertion of a now defective Tn into an ancestral mercury resistance Tn, which has additionally acquired two ISs. Tn21 also carries a genetic trap, which permits the acquisition of additional genes: the integron system. Integrons include an integrase gene, related to the λ -recombinase of bacteriophage λ . It also carries a flanking site equivalent to the λ attachment site, *att*, at which integration occurs. The acquired genes are generally promoterless and are located on small cassettes, which integrate site specifically into the *att* site where a resident promoter is appropriately located to drive expression.

Tn7

Transposon Tn7 (Figure 1(d)) is unusual in that it encodes five proteins necessary for its transposition and uses two transposition pathways: a site-specific insertion pathway and a more random pathway, which recognizes aspects of DNA structure in the target. One of the transposition enzymes (TnsB) is a DDE T_pase while a second (TnsA) shows similarity to restriction endonucleases. Two additional proteins (Tns D and E) are involved in target choice for each of the two pathways while the fifth (TnsC) provides a bridge between target protein and the T_pase. Tn7 also carries an integron system, which has permitted it to acquire resistance to trimethoprim among other antibiotic resistances. Other members of this group including different resistance genes have also been described.

Transposable bacteriophage

The first example of this type to be described was the temperate mutator phage Mu (Figure 1(e)), so-named because it inserts in a relatively random way and generates mutations during infection. Many different examples of mutator phages have been identified as either phage particles or during annotation of bacterial genome sequences. They are extremely large (>40 kbp) and relatively complex since they must encode for the enzymes and structural proteins involved in the bacteriophage lifestyle. They transpose using DDE enzymes.

Conjugative transposons

These were first discovered in Gram-positive bacteria as elements capable of transmitting tetracycline resistance from cell to cell and between bacterial species. Conjugative Tns (ICE for integrative and conjugative elements) use a site-specific recombination reaction for integration and excision. The enzymes are generally Y-T_pases, similar to the site-specific recombinases used by phage λ or the integrons. However, whereas λ and integrons show pronounced sequence specificity for integration, conjugative Tns are much less exacting in their choice of integration sites. They are large and, in addition to the genes involved in integration and excision and in antibiotic resistance, they carry genes required for conjugative transfer. Tn916 (Figure 1(f)) and Tn1545 are the best-characterized Tns of this type. Several examples of ICE encoding S-transposases have also been described.

Mechanism

Transposition requires precise cleavage at the Tn ends and their coordinated transfer into a target molecule. This is achieved through assembly of a nucleo-protein complex of defined architecture: the transpososome. This structure includes the T_pase, the Tn ends and target DNA. The signals for recognition and processing by T_pase are located in the Tn ends. Most bacterial ISs carry relatively simple IRs with a single T_pase-binding site. Other Tns show a complex constellation of sites often arranged differently at each end (e.g., phage Mu and Tn7).

DDE Enzymes

The majority of known T_pases is structurally related and carry a conserved triad of acidic amino acids, the DDE motif, which coordinate two divalent metal ions central to catalysis. Cleavage at the 3' ends of the element by an attacking nucleophile (generally H₂O) occurs to expose a free 3' OH group (Figure 2(a)). This nucleophile then attacks a 5' phosphate group in the target DNA in a single-step transesterification reaction (Figure 2(b)). The reaction, analyzed in detail for bacteriophage Mu, HIV, IS10, and IS50, occurs as an inline nucleophilic attack with chiral inversion of the phosphate group. The two metal ions are thought to act respectively as a Lewis acid and base in the reaction.

Concerted transfer of both Tn ends into the target site, while maintaining the correct strand polarity, results in joining each Tn strand to opposite target strands. Since the position of attack in target DNA is generally staggered, this generates short, complementary, single-strand regions, flanking the newly inserted element (Figure 2(c)). Repair by the appropriate host machinery generates a short duplication (direct repeat or DR) of defined length in the flanking target DNA (Figure 2(d)). The reactions do not require an external energy source nor do they involve a covalently linked enzyme-substrate intermediate. The donor Tn strand performs the cleavage-ligation steps in the target DNA and no cleaved target molecule is detected in the absence of strand transfer.

DDE enzymes cleave only one of the two DNA strands. An important feature of the transposition reaction is therefore the way in which the 5' end (second strand) is processed. Some Tns do not process the second strand and are, therefore, not separated from the donor molecule. Strand transfer generates a structure, which can be used as a replication fork. Replicative integration generates cointegrates or replicon fusions where the donor and target replicons are fused and separated at each junction by a directly repeated copy of the element (e.g., bacteriophage Mu, the Tn3 family; Figure 2, left column). Other elements shed their donor DNA prior to insertion. For some elements, the 3' OH generated by the first hydrolysis attacks the second strand to generate a hairpin form which then undergoes hydrolysis to regenerate an active 3' OH (e.g., IS10 and IS50; Figure 2, second column). Other TEs, at present generally of eukaryotic origin, generate an intermediate in which a hairpin structure is similarly formed on the flanking DNA. Yet others possess a second enzyme dedicated to cleavage of the second strand

Figure 2 Transposition mechanism of DDE elements. Transposon, inverted repeats, and flanking sequences are shown as green, red, and white, respectively. In target DNA (gray), direct repetitions (DR) are shown in white. Liberated 3'OH groups involved in subsequent strand joining reactions are shown (a, b). Left column: Replicative transposition as the result of single strand cleavage and transfer to create a replication fork (c). 2nd column: In the *IS10* (*IS50*) reaction pathways the 3'OH liberated in the initial hydrolysis attacks the opposite strand to generate a hairpin intermediate, liberating the transposon from its flanking donor DNA (a). A second hydrolysis regenerates the 3' OH (b). 3rd column: Double strand cleavage using two enzymes (e.g., *Tn7*). 4th column: For members of the *IS3* family (e.g., *IS911*), the 3'OH from a single-end hydrolysis directs a strand transfer reaction to the same strand to the other end of the element (a). The branched single-strand circle is resolved into a transposon circle by the host. Single-strand hydrolysis at each 3' end (b) generates a linear transposon, which can integrate in a target.

(e.g., *Tn7*; [Figure 2](#), third column). For members of several bacterial *IS* families (e.g., *IS3*, *IS21*, and *IS30*), the 3'OH liberated at one end of the *IS* attacks the other end on the same strand, generating a form in which one *IS* strand is

circularized. The entire *Tn* is then resolved into a free transient circular form by replication or recombination of the second strand. The *Tn* circle then undergoes efficient integration after single-strand cleavage at each end ([Figure 2](#), fourth column).

Non-DDE Transposases

The mechanism of transposition mediated by the other classes of T_pase is less well detailed than that of the DDE T_pases.

Y2 transposases

The Y2 T_pases, encoded by the IS91 family, show significant identity to the phage and plasmid rolling circle replicases in the regions covering their active sites. The characteristics of transposition are strikingly different from those of DDE-mediated events. ISs of this type do not exhibit terminal IRs, do not generate flanking direct repeats and insert into a conserved tetranucleotide, which is required for further transposition events. The right (but not the left) end and the tetranucleotide are essential for transposition. Moreover, deletion of the left end can result in one-ended transposition. In this case, the inserted fragment of donor DNA is flanked at one end (constant end) by the right end and at the other end by a conserved tetranucleotide sequence present elsewhere in the donor plasmid (variable end). In addition, circular single-stranded derivatives of IS91 have been observed and may represent transposition intermediates. While these data clearly support a polarized rolling circle mechanism, little is known about the strand transfer, which would assure transfer from donor to target site.

Y1 transposases

More is known about Y1 T_pases. These are found in the atypical IS200/IS605 family and are among the smallest known (~150 amino acids). In contrast to classical ISs but like the IS91 family, these elements do not carry IRs at their ends but small (20–25 nucleotides) subterminal hairpin structures located at some distance from the cleavage sites which are recognized by the Y1 T_pase. Cleavage occurs using a catalytic tyrosine residue as the nucleophile to generate a 5′ phosphotyrosine bond between T_pase and its DNA substrate. Transposition requires single-strand substrates and uses single-strand DNA intermediates. It proceeds in two steps: excision of a single strand circle followed by its insertion 3′ to a specific tetra- or penta-nucleotide which is also needed for further transposition. The reaction is strand specific (the top strand is active while the complementary bottom strand is refractory to the T_pase) and both excision and insertion occur preferentially at replication forks or on single DNA substrates created by DNA repair processes.

Y- and S-transposases

Although site-specific recombination reactions directed by S- and Y- recombinases are known in exquisite detail, the activities of the corresponding T_pases remain largely uninvestigated. By analogy, and in contrast to the DDE enzymes, it is assumed that catalysis involves the formation of a covalent enzyme substrate intermediate (Figure 3). In both cases, the element is excised precisely from the donor molecule.

For the Y-transposases, this would involve nucleophilic attack of the target phosphodiester bond by the active site tyrosine to generate a 3′-phosphotyrosyl bond exposing a 5′OH (Figure 3(a), left column). In a second step, the 5′OH attacks the phosphotyrosine bond at the opposite end to promote strand exchange (Figure 3(b), left column). Note that the

reaction of only one strand is shown here. Sequential reactions of cleavage and transfer on the opposite strand would then generate a circular intermediate (Figure 3(c), left column). Insertion is thought to occur by reversal of these reactions (Figure 3(d), left column).

For the S-transposases, recombination occurs by a concerted four-strand cleavage (Figure 3(a), right column) in which a catalytic serine residue attacks the target phosphodiester bond to generate a 5′ phosphoserine bond and to expose a 3′OH (Figure 3(b), right column). Strand transfer to generate a circular intermediate would occur by nucleophilic attacks of the covalent DNA-enzyme bonds by the 3′ hydroxyl ends generated by cleavage (Figure 3(c), right column). A second round of similar recombination reactions (Figure 3(d), right column) would then lead to insertion of the circular transposition intermediates (Figure 3(e)).

Target Choice

The choice of an insertion site can have important implications both for the Tn and for the host. Insertion into a specific target DNA sequence can provide a secure refuge for the Tn. For example, by using a specific sequence in a highly conserved gene in such a way that insertion does not disrupt the gene, transposon Tn7 is assured an insertion site, which does not affect the fitness of the host and occurs in many bacterial species. On the other hand, in excluding insertions into other DNA sequences, this strategy precludes the capacity of the element to generate mutations or to activate or sequester genes and thus to generate genetic diversity. Different transposons exhibit a variety of different strategies for selecting a target. On a genome scale, most transposons appear to insert randomly. However, when analyzed at the nucleotide level, most show some degree of target preference. Insertion can be sequence specific, with target sequence lengths varying from a few to many nucleotides, or show regional preferences, for example, GC- or AT-rich DNA segments, probably reflecting more global parameters such as local DNA structure. Other factors which have also been implicated are: the degree of supercoiling, vegetative and conjugative (transfer) DNA replication (e.g., both Tn7 and members of the IS200/IS605 family are preferentially inserted into extant replication forks), transcription and protein-mediated targeting to, or exclusion from, transcriptional control regions. In addition, some transposons show a preference for insertion close to sequences resembling the transposon end. Others exhibit the converse behavior: exclusion of insertions close to a resident end. This phenomenon, transposition immunity, can act over many kilobases of DNA. For Tn7 and Mu, it has been shown that this is accomplished by a second Tn-encoded protein (in both cases a DNA dependant ATPase), which binds target DNA. Briefly, for phage Mu, the T_pase MuA is capable of stimulating dissociation of the DNA-dependent ATPase, MuB from DNA. Thus, MuA bound to a Tn end resident in the target molecule is thought to provoke disassembly of MuB from neighboring DNA with a probability, which decreases as the distance increases.

Clearly, many insertion preferences must reflect constraints in the architecture of the synaptic complexes formed between the Tn ends, the target DNA and the T_pase.

Figure 3 Reaction mediated by Y-transposase and S-transposases. Left column: Transposon and flanking sequences are shown as green and white, respectively. The active site residue Y or S is shown within a yellow circle. Y-transposase nicks one transposon strand (here on bottom strand) at both ends (a) and forms covalent 3' phosphotyrosine intermediates (b). The liberated 5' OH attacks the phosphotyrosine linkage at the other end (arrows) to circularize one transposon strand (b). The same reaction is performed on the top strand to regenerate the donor and a circular intermediate (c). Further cleavage and transfer (d) is presumed to result in an insertion into target DNA (e). In contrast to site-specific recombination, the Y-transposase exhibits low sequence specificity for the target site. Right column: S-transposase catalyzes concerted double-strand breaks at both ends (a), forming covalent 5' phosphoserine intermediates (b). After a switch of strands, the 3' OHs attack the phosphoserine bonds in the opposite end (b), resulting in a circular intermediate (c). The same process (d) permits insertion of the element in a target (e). For both pathways, strand transfers reconstituting donor molecule (b and c) are shown by dotted arrows.

Regulation

Transposable elements are very highly regulated and have evolved a variety of perspicacious regulatory mechanisms. Apart from the temperate transposable bacteriophages, which

possess a highly efficient transposition mechanism during their lytic development, transposition is not an efficient event. A given transposable element generally possesses an ensemble of regulatory mechanisms, which can differ in detail from even closely related elements.

Regulation can be at the gene expression level or at the level of T_pase activity. A combination of weak promoters and poor ribosome-binding sites can limit transcription and translation while secondary structures, which sequester translation initiation sites and involve RNA sequences upstream and downstream of the T_pase promoter, can be present to prevent accidental activation by impinging transcription (IS10, IS5). Some elements produce a small antiRNA also capable of sequestering translation initiation signals, which acts as a negative control component (IS10). Another mechanism to control transposition activity has been documented in elements whose transposition involves a circular or a dimeric intermediate (IS911, IS2, IS30, IS21). Here, the weak endogenous promoter can provide low levels of T_pase to enable low-frequency formation of the Tn circle. However, the IR–IR junction formed in both Tn dimers and circles creates a strong promoter by virtue of a –10 promoter element oriented inward at one IR and a –35 element oriented outward in the other. This boosts T_pase synthesis resulting in cleavage, disassembly of the junction promoter and insertion of the Tn, which then again assumes a low level of T_pase expression from the indigenous promoter. Transcription termination signals within the T_pase *orf* or posttranslational processing might also regulate T_pase expression, although these mechanisms have not been investigated in detail. Another relatively common regulatory mechanism involves programmed translational frameshifting (IS1 and IS3 families). Here, the T_pase is distributed over two consecutive *orfs*, and frameshifting serves to generate a fusion protein including the products of the upstream *orf*, which generally carries DNA-binding and multimerization functions, and the downstream *orf*, which can include the catalytic site. The product of the upstream frame in these cases generally serves a regulatory role. For certain elements, posttranslational proteolysis might also be used to generate small regulatory proteins. IS50 also generates a protein, Inh, using a second promoter located downstream from the T_pase promoter and representing an N-terminal truncated derivative of the T_pase. Inh acts as a T_pase inhibitor.

Regulation can also occur at the level of T_pase activity. The differential arrangement of T_pase-binding sites at each of phage Mu and Tn7 (and perhaps members of the IS21 family) permits a functional distinction and presumably favors the use of one left and one right end *in vivo*. Moreover, in many cases, T_pase bound at one end catalyzes strand cleavage at the partner end. This ‘trans’ cleavage assures that the correct complex has been assembled before transposition can take place. For Tn7, the cleavage and strand transfer reactions require the presence of the target DNA molecule.

An additional level of control of T_pase activity is reflected in the observation that these enzymes often prefer to act on the copy of the element from which they are synthesized. In other words, they exhibit a preference for activity in *cis*. Several nonexclusive explanations for this behavior are apparent and *cis* activity is likely to involve a combination of different effects. One invokes cotranslational binding in which a nascent T_pase protein is capable of correctly folding its DNA-binding domain and binding to Tn ends before synthesis of the entire protein is accomplished. This is a mechanism which appears to act in the case of IS911 and probably for many other ISs. A second model invokes T_pase stability and it has been demonstrated in at least

one case, IS903, that the Lon protease plays a crucial role in *cis* activity. There are also strong indications that protein chaperones such as GroE S/L and DnaK/J are involved in regulation at this level.

Other host factors can also intervene at different regulatory levels. DAM methylase is involved in regulating T_pase expression and the recombination activity of the ends both IS10 and IS50. DNA architectural proteins such as IHF, Fis, and Hu have also been implicated in assuring the correct assembly of the transpososome. Moreover, IHF has been implicated in driving the molecular transitions leading to strand cleavage in IS10. Other factors such as RecBC, DnaA, Acyl carrier protein, and ribosomal protein L29 have also been implicated in the transposition behavior of various elements, but the exact details remain to be elaborated.

Eukaryotic Transposons

Although this section is devoted to prokaryotic elements, it is important to note that eukaryotes generally carry large numbers of both intact and truncated transposable elements. These constitute over 40% of the human genome and somewhat less in Arabidopsis. There are many similarities between prokaryotic and eukaryotic elements. A major group is the Tc/mariner superfamily whose members are similar to bacterial ISs. They carry terminal inverted repeats and encode a DDE or, in this case, a DDD group T_pase and resemble the IS630 family of bacterial elements. Many eukaryotic genomes, especially those of plants, harbor extremely high numbers of truncated derivatives, similar to those found in bacteria, in which the T_pase gene appears to have been deleted leaving both IRs. These elements have also been called miniature inverted repeat transposable elements (MITEs) and can presumably be mobilized by the full length copies of the elements located elsewhere in the genome.

Another major group, which is limited to eukaryotes, are the retro-viruses and LTR-retro-Tns, which pass through an RNA intermediate during their (viral) life cycle. Integration into the host genome occurs through a double-stranded cDNA intermediate and uses DDE group integrase (IN).

The immunoglobulin V(D)J recombination system represents another important element in vertebrates. Here, rearrangements involve two host proteins, RAG1 and RAG2. The RAG1 recombinase is related to DDE T_pases. An interstitial DNA segment (signal sequence) is excised to permit the rejoining of two flanking sequences (coding sequence). In a similar way to IS10 and IS50, recombination involves the formation of a hairpin intermediate. In this case, however, the hairpin is generated on the flanking DNA rather than on the excised fragment.

A third large family of eukaryotic elements is the hAT superfamily. Although the nature of their T_pase is not clear and little work has yet been undertaken concerning their transposition (which includes *hobo* and *Hermes* from insects, *Ac* and *Tam3* from plants), it seems probable that they have adopted a V(D)J-type of recombination mechanism.

Eukaryotes also harbor other families of IS-like elements including the P element of *Drosophila melanogaster* whose mode of transposition has received much attention due to its use in

mutagenesis, the CACTA family, which includes the plant transposons Tam1 and Tam1, and the En/Spm family.

Other newly recognized classes of eukaryotic elements are the helitrons, which resemble rolling circle Tns of the IS91 family, and Cryptons, DIRS1, and kangaroo elements, which appear to encode Y-transposases.

In addition to eukaryotic elements, which transpose using a DNA intermediate including the retro-viruses, a large class of Tns, which transpose by a completely novel mechanism, has also been identified. These are the target-primed (TP) retro-Tns in which an RNA intermediate is copied into its DNA target via reverse transcription.

Glossary

Bacteriophage A virus or phage that can infect bacteria.

Epigenetic Inheritable properties that are caused by mechanisms other than changes in the underlying DNA sequence.

Exaptation An evolutionary phenomenon that a trait is selected for one function and adapts to perform another function.

Extrachromosomally primed (EP)

retrotransposon Retrotransposon that is reverse transcribed from genomic RNA template prior to association of the cDNA with the integration site.

Hybrid dysgenesis The high rate of mutation in germline cells of *Drosophila* strains resulting from a cross of males with autonomous P elements (P Strain/P cyotype) and females that lack P elements (M Strain/M cyotype). Hybrid dysgenesis causes sterility in the F1 progeny.

Integrase Enzyme that recombines phage or transposable element DNA into a host genome through a polynucleotide transesterification reaction.

Intrinsic immunity A set of cellular-based anti-viral defense mechanisms, notably genetically encoded proteins which specifically target eukaryotic retroviruses. Intrinsic immune proteins are usually expressed at a constant level, allowing a viral infection to be halted quickly.

Retrotransposon Transposon that replicates through the reverse transcription of a RNA copy.

Reverse transcriptase (RT) Enzyme that uses a RNA template to synthesize DNA

RNA interference (RNAi) Pathway through which the Dicer complex generates RNAs of 21–30 nt in length that target other RNAs for translational repression or degradation via the argonaute subunits of the RNA-induced silencing complex (RISC). RNAi can also lead to repression of transcription through modification of DNA or chromatin.

Target-primed (TP) retrotransposon Retrotransposon that reverse transcribes its genomic RNA at the site of integration primed from 3'-OH in host DNA at the integration site.

Target site duplication (TSD) Short DNA sequences present in one copy at the site of integration and directly repeated on both sides of the integrated copy of the transposon. This flanking direct repeat is generated during repair of the gaps created by staggered strand-transfer sites of the transposon DNA to host DNA.

Transposon Nonviral sequences of DNA mobilized through RNA- or DNA-based mechanisms.

Wild type Versions, for example, of transposons or organisms that are in the native state and implied to be functional.

Introduction

Transposons or mobile DNAs are sequences that can move within the genome of a single cell. Mobile genetic elements were discovered by Barbara McClintock in the 1940s, for which she was awarded the Nobel prize in 1983.

Transposons are classified as retrotransposons or DNA transposons based on the mechanisms by which they mobilize. Retrotransposons or class I transposons are transcribed into RNA, reverse-transcribed into a complementary DNA (cDNA), and integrated into the host genome. DNA or class II transposons mobilize via DNA replication-coupled integration into a new site (replicative transposition) or via excision of element DNA and integration at a new site (cut-and-paste). In either case the junctions with host DNA are offset by 4–9 nt on the two host DNA strands resulting in a characteristic direct repeat of the offset sequence flanking the inserted element. This repeat referred to as the target-site duplication (TSD) is a signature of transposon insertions. Insertion site patterns of elements range from highly specific to relatively nonspecific, depending upon the element. These patterns affect the impact of elements on host genome function.

RNA and DNA elements are found in all three domains of living organisms, *Archaea*, *Bacteria*, and *Eukarya* (Figure 1). In model organisms with relatively compact genomes, including bacteria (*Escherichia coli*), yeast (*Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*), fruit fly (*Drosophila melanogaster*), nematodes (*Caenorhabditis elegans*), and mustard weed (*Arabidopsis thaliana*), transposable elements comprise less than 10% of the genome, with variation in the representation of class I and class II elements. For example, *Saccharomyces*, *Drosophila*, and *Arabidopsis* contain mostly class I elements, but bacteria and worms contain mainly class II elements. It is not understood what accounts for this difference in representation of elements. However, one important distinction is that expansion of class I element copy number is independent of host cell replication. As a result, in some organisms, retrotransposons that have undergone expansion can become a significant factor contributing to larger genome size. For example, the human genome, which is 10 times larger than the fruit fly genome, has less than twice as many genes, and is almost half retrotransposons. In some plants there is an even greater proportion of retrotransposons. For example, the maize genome is 100 times larger than the fly genome and is 85% retrotransposons.

Figure 1 Percentages of model organism and human genomes composed of retrotransposons (class I) and DNA transposons (class II). Organisms are maize, *Zea mays* ssp. *mays* L; wheat, *Aegilops tauschii*; human, *Homo sapiens*; mouse, *Mus musculus*; mustard weed, *Arabidopsis thaliana*; fruit fly, *Drosophila melanogaster*; budding yeast, *Saccharomyces cerevisiae*. Genome sizes in bp are included in parentheses for each species. Percentages of transposons are shown as bars in various lengths, with the scale bar shown at the bottom. Color scheme: gray for non-transposon regions, light red for LTR retrotransposons, dark red for non-LTR retrotransposons and blue for DNA transposons.

Retrotransposon Diversity

Retrotransposons can be categorized based on differences among retrotransposition mechanisms which correlate with differences among reverse transcriptase (RT) and retrotransposon genome structures (Figure 2). RT itself is the most conserved of retrotransposon proteins. Mechanistically, there is a fundamental distinction between retrotransposons for which reverse transcription is primed from retrotransposon-associated RNA (extra-chromosomally-primed (EP)) and those for which reverse transcription is primed from host DNA (target-primed (TP)). Examples of the former class include direct, long terminal repeat (LTR) retrotransposons (retrovirus-like), and tyrosine recombinase (YR) elements. Examples of the latter class include the site-specific R2-type elements, long interspersed elements (LINEs), Penelope-like elements (PLEs), and group II introns of bacteria and organelles of lower eukaryotes and higher plants. These elements are discussed in more detail below.

Two additional bacterial classes of sequences, segments of which are replicated by reverse transcription, are worthy of mention and provide a hint of the richness of biology contributed by reverse transcription-related processes. These are bacterial retrons and diversity-generating retroelements (DGRs). Retrtons have similarity to the EP elements described above. The most extensively characterized retron is *E. coli* multicopy single-stranded DNA (msDNA). Retrtons encode RT but reverse transcribe only a segment of the retron transcript primed from a guanidylate 2'-hydroxyl in the template RNA itself and then degrade the template portion of the RNA leaving a product in which RNA and DNA are covalently linked. In the genomic form, retrtons typically occur as passengers in temperate bacteriophage, and the mechanism through which the extra-chromosomal copies integrate into phage or genomic DNA is not known, nor is any functional benefit of the retron known.

DGR elements have similarity to the TP elements described above. The DGR encodes two copies (template repeat and variable repeat) of a subdomain of a *Bordetella* phage tropism protein as well as RT. Reverse transcription of the template repeat generates a cDNA which is hypervariable at each

adenine position. This copy is recombined back into the genome at the site of the variable region copy in a homology-dependent process. DGR confers advantage to the phage in responding to changes in availability of its *Bordetella* host receptor protein.

TP and EP families of retrotransposons each include members that are incapable of autonomous retrotransposition (nonautonomous) in addition to the self-mobilizing elements (autonomous), but for which the RNA transcript can be mobilized *in trans* by proteins encoded in autonomous elements. Interestingly, in the case of TP elements – the proteins of which function efficiently *in trans* to the element genomic RNA – nonautonomous elements are either degenerate copies of active elements or highly-abbreviated copies containing minimal sequences required *in cis* in the RNA and cDNA for replication and integration, respectively. In the case of EP retrotransposons, the proteins of which function most efficiently *in cis* to the genomic RNA, certain elements such as LINEs support mobilization of small unrelated sequences transcribed by RNA Pol III.

We have mentioned here the major classes of elements and some fundamentally different pathways by which they retrotranspose. Prokaryotic cells were used to exemplify nonconventional retrotransposon systems that allow directed feedback from RNA into the genomes of host organisms. One of the distinguishing properties of reverse transcription is its error-prone nature, and of course, as genomic parasites, retrotransposons are relatively free to diversify. The advent of high-throughput sequencing has driven a rapid increase in transposon discovery including novel varieties, suggesting that we have only begun to sample the diversity of these fascinating denizens of our genomes.

Extrachromosomally Primed Retrotransposons: Replication and Integration

LTR Elements

EP retrotransposons are transcribed into RNA, which templates production of proteins required for retrotransposition and serves as the template for reverse transcription. LTR elements

Extrachromosomally-primed elements

Target-primed elements

Bacterial retroelements

Figure 2 Genome structures of representative retrotransposons. Extrachromosomally-primed retrotransposons include LTR retrotransposons (e.g., *S. cerevisiae* Ty1 and Ty3) and tyrosine recombinase (YR) retrotransposons (e.g., *Dictyostelium discoideum* DIRS1). Target-primed retrotransposons include non-LTR retrotransposons – R2, LINES, and SINES (e.g., *Drosophila simulans* R2, *H. sapiens* LINE-1 (autonomous) and Alu (non-autonomous)) – Penelope-like retrotransposons (PLEs) (e.g., *Drosophila virilis* Penelope), and group II introns (e.g., *Lactococcus lactis* LI.LtrB). Bacterial retrotransposons include retrons (e.g., *E. coli* msDNA; retron RT-coding region is not to scale) and diversity-generating retroelements (DGRs) (e.g., *Bordetella* BPP-1).

are named after the LTRs flanking one (*S. pombe* Tf1) or two open reading frames (ORFs) (*S. cerevisiae*, Ty1, Ty3) in the DNA copy. These upstream and downstream repeats contain the promoter and terminator signals, respectively, for production of the genomic RNA. The central ORF(s) encode polyproteins that are processed into structural (capsid and RNA binding protein) and enzymatic (protease (PR), RT, and integrase (IN)) proteins necessary for retrotransposition (Figure 2). The budding yeast Ty retrotransposon (e.g., Ty1 and Ty3) replication cycle (Figure 3) illustrates replication of an LTR retrotransposon. Levels of the polyproteins are tightly regulated, resulting in a high ratio of structural to catalytic protein

that facilitates formation of virus-like particles (VLPs). In the case of single ORF elements, this ratio is maintained by regulated processing. In the case of overlapping ORFs, translation of the first ORF occurs normally, but similar to retroviruses, the second ORF is translated dependent upon programmed frameshifting that occurs at the downstream end of the first ORF. Because frameshifting is not efficient, a relatively low amount of structural protein fused to catalytic protein is produced. This not only means that protein is produced in appropriate proportions, but catalytic protein domains are included in the VLP by virtue of their fusion to structural protein. The RNA-binding domain of the structural protein binds to motifs in genomic

Figure 3 The replication cycle of a Ty LTR retrotransposon. Ty is transcribed in the nucleus to produce an almost full-length, polyadenylated RNA that is exported to the cytoplasm. This RNA serves translation template and genomic RNA functions. The upstream frame is designated *GAG* and downstream frame is *POL*, named after the analogous retrovirus ORFs. It is translated into Ty proteins: Gag and Gag-Pol that assemble around the Ty genomic RNA to form virus-like particles (VLPs). Upon assembly, PR cleaves the Gag3 into capsid and RNA-binding proteins and Gag-Pol polyprotein into PR, RT, and IN within the VLPs. Reverse transcription occurs associated with VLPs. The preintegration complex is imported into the nucleus, and IN mediates integration into new chromosomal locus, thereby creating a new copy of the retrotransposon.

RNA resulting in its assembly into VLPs. VLP formation activates the encoded PR which processes structural protein into capsid and RNA-binding protein and the downstream domain into PR, RT, and IN.

In association with VLP components, genomic RNA is reverse transcribed into cDNA through a process similar to that used by retroviruses. Transcription of the genomic RNA initiates in the upstream LTR 5' of the position of termination in the downstream LTR resulting in a RNA containing only one complete LTR copy. Therefore, reverse transcription must regenerate complete LTR sequences at each end. For most characterized LTR retrotransposons, the primer for reverse transcription is a host tRNA that anneals to a short complementary sequence just outside of the LTR sequence near the 5'-end of the genomic RNA. Through a process involving terminal transfers of cDNA intermediates, reverse transcription regenerates complete LTRs at each end of a product duplex cDNA. In a reaction catalyzed by the IN protein, hydroxyl groups at the two 3'-ends of this extrachromosomal duplex DNA attack phosphodiester bonds on the two target DNA strands. Energy is conserved in this polynucleotide trans-esterification reaction and adenosine triphosphate (ATP) is not required. Retrotransposon IN proteins have an active-site motif in common with other enzymes that catalyze polynucleotide trans-esterification reactions, such as DNA transposon recombinases. DNA copies of elements that are integrated in this way terminate in an inverted repeat in the sense strand. This is because each end must be similarly recognized by the IN protein. In addition to this structure, the specific sequence 5'TG...CA3' is also highly conserved. Because the target DNA is not only duplex, but helical, the joints between the element and the host on each strand are slightly offset, creating gaps in the product DNA on the nonjoint strands. These gaps are filled in and ligated by host enzymes, generating characteristic TSDs and completing the integration reaction.

Based on the similarities of retrovirus and LTR retrotransposon genome structure and function, ancient retroelements related to Ty3/gypsy may have captured host genes, adapted them for functions to enable cellular egress and entry, and emerged as retroviruses. Historically, LTR retrotransposons were divided groups designated according to characterized members in yeast and *Drosophila*, respectively: Ty1/copia, and Ty3/gypsy. Ty1 and Ty3 groups differ from each other on the order of the proteins encoded in *pol* gene. Based on this distinction and coding sequence similarity, retroviruses most closely resemble the Ty3/gypsy group. Specific elements in this group (e.g., the gypsy element of *Drosophila*) encode envelope proteins that have been shown to mediate extracellular infection, thus blurring the distinction between retrotransposons and retroviruses. Subsequently, an additional group was discovered in animals and also designated after founding members *pao/BEL*. The list of LTR retrotransposons is likely to continue to grow.

A high proportion of defective full-length LTR retrotransposons is observed in genomes and could theoretically be mobilized *in trans* by proteins encoded by wild-type elements. Many isolated LTRs also exist in genomes. These are generated by recombination between intact retrotransposon terminal LTRs (resulting in deletion of the intervening coding sequence). However, because the primer is typically not contained in the LTR, they do not generate transcripts with the appropriate sequences to allow reverse transcription and therefore are not mobilized by *trans*-acting autonomous functions. Families of nonautonomous, LTR elements with large internal deletions that appear to have been mobilized have been identified in plants. These include large retrotransposon derivatives (LARDs), which contain long noncoding sequences; terminal-repeat retrotransposons in miniature (TRIMs), which contain only very short sequences; and *Morgane*, which contains *pol*-like partial sequences flanked by LTRs.

Figure 4 The replication cycle of human LINE-1 (L1) non-LTR retrotransposon. L1 RNA is transcribed and transported to the cytoplasm, where it is translated into ORF1p and ORF2p. The L1 proteins and RNA assemble into a ribonucleoprotein particle which is then transported into the nucleus. L1 copies its RNA into DNA at a new locus via a process called target-primed reverse transcription (TPRT).

Tyrosine Recombinase Elements

The LTRs of EP retrotransposons are typically direct repeats. However the LTRs of YR EP retrotransposons also occur as inverted repeats. YR elements encode structural protein and RT, but rather than a retrovirus-like IN, they encode an enzyme more similar to a bacteriophage lambda IN. This IN mediates integration of lambda bacteriophage at specific attachment sites in the bacterial genome via an intermediate in which DNA is covalently attached to an active site tyrosine. The DIRS1 retroelement from the slime mold *Dictyostelium discoideum* is representative of the YR class of retrotransposons. DIRS1 RNA is thought to be reverse transcribed into a circular cDNA by a mechanism involving internal complementary repeats (ICRs). The circular cDNA is proposed to be integrated into the host genome by YR-catalyzed recombination YR.

TP Retrotransposons: Replication and Integration

R2-Type Elements

The most extensively studied R2-type elements are found in the repeated ribosomal RNA genes of insects where the genomic RNA is actually processed from the rRNA. A generic version of TP retrotransposition is illustrated in Figure 4. The transcript has 5'- and 3'-untranslated regions flanking a single ORF that encodes a multifunctional protein containing an RT domain followed by an EN domain with similarity to type II restriction endonucleases (ENs). Genomic RNA is imported into the nucleus complexed with the multifunctional protein. The EN activity creates a 3'-end from which reverse transcription of the genomic RNA is primed. In a less well-understood reaction, the second strand of target DNA is also nicked and used to prime synthesis of the second strand of the integrated copy. Depending on the position of the second-strand nick with respect to the first-strand nick, either a TSD or a target-site deletion results. Studies of the R2 element led to formation of the TP reverse transcription (TPRT) model of replication for the broader class of TP elements.

Long- and Short-Interspersed Elements (LINEs and SINEs)

In contrast to the R2-type elements, LINEs are found in a broad distribution of species and have a preference for AT-rich sequences. Full-length LINE elements are 4–7 kb in length. Genomic RNA is produced by transcription from an internal RNA Pol II promoter. The predominant human LINE element, L1, is a well-studied example. L1 contains 5'- and 3'-untranslated regions flanking two ORFs. The upstream ORF encodes a protein (ORF1p) with nonspecific RNA-binding and structural domains and the downstream ORF encodes a protein (ORF2p) with apurinic endonuclease (AP) and RT domains. The mechanism of L1 integration is generally similar to the TPRT mechanism described above for R2. However, because insertions are templated by a polyadenylated RNA, they are distinguished from R2 and LTR retrotransposon insertions by the presence of a downstream poly (A) tract on the coding strand. It is notable that most L1 integrants are 5'-truncated and nonfunctional for further replication. This property has been attributed to non-processive L1 reverse transcription and to microhomology between L1 and the target site. There are more than 5×10^5 copies of L1 in the human genome, of which less than 100 are capable of autonomous retrotransposition. Because LINE proteins act predominantly on the RNA from which they are translated, they do not complement the mobility of defective LINES efficiently.

Nonautonomous short interspersed elements (SINEs) are noncoding sequences of 80–400 bp. They contain internal RNA Pol III promoter elements and are derived from ancestral Pol III-transcribed genes for structural RNAs. Interestingly, the SINE-source Pol III-transcribed genes differ among species. The major SINE in primates is the Alu element. These are derived from tandem repeats of the gene for the signal recognition particle 7SL RNA. In many species, SINEs are derived from tRNA genes. There are $\sim 1.4 \times 10^6$ copies of Alu in the human genome, which comprise greater than 10% of the genome. These nonautonomous elements are mobilized by proteins encoded by autonomous LINES. Exactly how they overcome the *cis*-bias of LINES is not known, but it may have to do with

the association of the Alu signal recognition particle RNA with translating ribosomes and nascent LINE proteins. Similar to LINES, these elements display a downstream poly(A) track on the coding strand and are flanked by TSDs of variable lengths. A second active class of primate SINE, called SVA, is about 2 kb in length and represents a composite of a hexameric repeat, a fragmentary Alu-like sequence repeat, a region containing a variable number of tandem repeats of 30 to 50 bp, and part of the envelope gene and LTR of a human endogenous retrovirus. Insertions of SVA sequence also have a downstream poly(A) tract on the coding strand. There are ~5000 SVA elements in the human genome. Similar to Alu elements, they are also thought to be mobilized by LINE activity. Together LINES and SINES constitute almost half of the human genome.

Penelope-Like Elements

PLEs are exemplified by Penelope of *D. virilis* and Athena of *Bdelloid rotifers*. Intact copies contain a single ORF encoding two domains, RT and EN, although the latter is not consistently present. The PLE RT is very distantly related to those of other elements and can be disrupted by an intron, which is a surprising feature for a retrotransposon. Although PLE can have LTRs, in either direct or inverted orientation, many copies are 5'-truncated and have variable-length TSDs. The 5'-truncation of characterized copies and variable presence of the EN domain together with the concentration of this element in telomeric regions in some organisms is consistent with a TP mechanism of replication.

Prokaryotic and Organellar Retrotransposons

TP retrotransposons include the group II introns found in bacterial, as well as organellar genomes of lower eukaryotes (mitochondria) and plants (mitochondria and chloroplasts). These elements mobilize via efficient site-specific retrohoming into double-stranded DNA or inefficient retrotransposition into single-stranded DNA sequences resembling retrohoming sites and associated with replication forks. Mobilization by the former mechanism requires the multifunctional intron-encoded protein (IEP) that has four domains RT, X, DNA-binding (D), and EN. RT and X provide maturase activity that stabilizes the intronic RNA structure required for splicing; X and EN domains are required for retrohoming. EN cleaves the nonspliced DNA strand to create the site for 3'-end priming of the reverse transcribed copy template by the integrated intronic RNA. The RT domain is required for reverse transcription of the intronic RNA. The intronic RNA is subsequently degraded by host RNase H activity. Retrotransposition mobilization into single-stranded DNA is EN independent as reverse transcription of the intron template is primed from lagging-strand replication intermediates.

Integration Site Preference

Genome-wide investigation of retrovirus insertion sites showed that specific viruses exhibit bias toward the promoter or transcribed regions of genes. In contrast to retroviruses,

many retrotransposons display a high degree of insertion site preference, possibly reflecting a requirement to be tolerated by the host for long periods. Integration patterns range from relatively little specificity to a high degree of sequence specificity. These differences are based on the proteins mediating integration, including site-specific restriction enzyme-like EN proteins and IN proteins that interact with host transcription factors or chromatin proteins or in the absence of IN or EN functions, targeting patterns based on availability of DNA ends. Although there may be other influences, it is safe to say that targeting reflects the influence of EN or IN proteins associated with the retrotransposon.

Extrachromosomally Primed Element Targeting

At the most extreme end of the spectrum, the *Drosophila* LTR retrotransposon ZAM IN recognizes a specific target sequence and, similar to a type II restriction enzyme, integrates adjacent to the sequence 5'CGCGCg3' (lowercase 'g' indicates a 50% occurrence of that base). Compared to retrovirus IN homologs, many LTR retrotransposon IN proteins, including those of fungal elements, have extended carboxyl-terminal domains, and several have been shown to mediate interaction and therefore targeting by host transcription factors or chromatin proteins. The *S. cerevisiae* retrotransposons Ty1–4 insert preferentially at Pol III-transcribed genes. Ty1, 2, and 4 are found within 750 bp upstream of these genes, while Ty3 IN interacts directly with Pol III transcription factor subunits and integrates into the transcription initiation site. Because Pol III promoters are internal, this mechanism of specificity tends to insure against detrimental effects of gene disruption. Similarly, the *S. pombe* Tf1 IN interacts with leucine zipper transcription factors causing Tf1 to target the promoter regions of Pol II-transcribed genes. Other elements target heterochromatic regions via interactions with chromatin proteins. Ty5 IN interacts with the Sir4-silencing protein found at silent mating-type loci and telomeres. The fungal MAGGY element IN contains a chromo-domain within the carboxyl-terminal domain of IN that interacts with methylated H3K9, biasing MAGGY integration toward heterochromatic regions. Overall, these patterns are consistent with minimizing disruption of host cell functions and conducive to retrotransposon proliferation.

TP Retrotransposon Targeting

Diverse mechanisms underlie the insertion patterns of TP retrotransposons. At one extreme is the R2-type non-LTR element which encodes an EN domain related to type II restriction ENs that creates the priming site by cleaving adjacent to its binding site within the rDNA repeats of host organisms. Lesser specificity is illustrated by the LINE type of non-LTR elements which derive EN function from an AP. These elements display bias for AT-rich sites favoring the consensus 5'TTTT/AA3' with cleavage at T/A. This pattern allows pairing of the template poly(A) tail with the priming site. Group II intron RNAs integrate by specific reverse splicing at homing sites. However, in this case, the reaction is mediated by an RNA structure stabilized by the IEP maturase rather than by an enzyme as in the case of the site-specific R2-type elements.

Other classes of TP elements occur in forms that can transpose in the absence of EN activity. The insertion patterns of these elements are influenced by the availability of DNA structures conducive to reverse transcription priming. This mechanism is dramatically illustrated by the autonomous TART element of *Drosophila*. Because DNA polymerase requires a free 3'-OH primer end, there must be a special mechanism for replication of the 5'-ends of linear chromosomal DNA. In most eukaryotic species, this function is performed by telomerase. Telomerase is an RT related to non-LTR retrotransposon RT. It extends the 3'-ends of chromosomes by copying a short guide RNA with which it is complexed. However, telomerase is lacking in *Drosophila*. Rather, retrotransposons such as TART exploit the 3'-OH of chromosomal DNA as the primer, and in so doing extend chromosomes and provide the telomeric replication buffer. TART elements occur associated with defective Het-A elements and are thought to complement Het-A mobility *in trans*. Some isolates of PLE lack EN and are similarly found in telomeric regions. TP elements lacking EN can also exploit available lagging strand 3'-ends at replication forks. The best-understood example of this is group II intron retrotransposition.

Overall, both EP and TP retroelements display some degree of target specificity. This is likely to reflect, particularly in lower eukaryotes with a greater density of coding sequence, the benefits to a genomic parasite of minimizing disruption of host functions.

Regulation of Retrotransposons

Because retrotransposon amplification is potentially harmful, host cells have developed extensive mechanisms for controlling retrotransposition. These operate at the levels of transcription, mRNA stability, translation, and protein stability and modification. Only EP LTR retrotransposons have been identified in the nuclear DNA of the single-cell model organism *S. cerevisiae*. The EP LTR retrotransposon Ty1 and Ty3 illustrate some of these fundamentally different types of regulation. For example, Ty3 is expressed only during the brief window of the yeast mating cycle. Transcription is low in haploid cells and repressed in diploid cells, but is induced more than 50-fold in mating haploid cells. Transposition occurs after diploid cells begin to replicate. Ty1 transcripts are the most abundant mRNAs in *S. cerevisiae*, but production of active VLPs is downregulated by anti-sense RNA and proteolytic degradation. DNA maintenance factors also control retrotransposition of Ty elements. This reflects cDNA degradation by some DNA damage surveillance factors as well as stimulation of Ty1 transposition by DNA repair checkpoints. The heterochromatin-targeting Ty5 illustrates yet another level of regulation. In this case, stress relaxes the stringency of its targeting, allowing it to proliferate to novel insertion sites. Thus, these elements in a primitive eukaryote transpose during brief developmental windows and during times of stress, potentially favoring evolutionary persistence of both host and element.

A mechanism of retrotransposon regulation which is extremely widespread, but for which functions do not occur in *S. cerevisiae*, is RNAi. Retrotransposons have a propensity to generate double-stranded RNA. Some of these can be attributed to sense and antisense promoters within the retrotransposon

itself. However, as discussed above, in many organisms preferential insertion of retrotransposons results in chromosomal clusters of elements. Because insertions can occur in both orientations, readthrough transcription even at a low level can generate anti-sense RNAs available to duplex with sense RNAs. This is particularly true of LTR retrotransposons which have promoters in the upstream and downstream LTR sequences. These duplex retrotransposon-related RNAs provide substrates for the Dicer complex, which cleaves duplex RNAs into RNAs 21–30 nt in length. Generation of these RNAs is potentially amplified by cellular RNA-dependent RNA polymerases. One strand of the processed duplex is taken into the RNA-induced silencing complex (RISC) and used as a guide RNA by the Argonaute (Ago) subunit to target complementary RNA sequences for post-transcriptional degradation or through less well-understood translational repression mechanisms. Furthermore, specialized Argonaute proteins, including the Piwi Argonaute proteins, are active in controlling retrotransposition in germ cells where it would have profound consequences in the form of heritable insertions.

Animal cell methylation of CpG in DNA and chromatin modification, particularly methylation of lysine 9 of histone 3 (H3K9), are important mechanisms for repression of transcription. Because these modifications of DNA and chromatin can feedback to target maintenance of modifications, they are heritable without changes in coding DNA. Such regulation is referred to as epigenetic regulation. Epigenetic regulation is important for cellular differentiation during development. A particular type of epigenetic regulation is imprinting, in which maternal and paternal alleles are differentially methylated. EP LTR retrotransposons and TP LINE retrotransposons are repressed by DNA and chromatin modification. Furthermore, they may be differentially repressed in maternal and paternal germ cells. Mutations in components of the RNAi pathway relieve at least some of this repression, indicating that RNA components of this pathway can direct modification of both DNA and chromatin to retrotransposon sequences.

Retrotransposons may also have driven development of cell-based or intrinsic immunity functions. One example is the apolipoprotein B RNA-editing catalytic polyprotein (APOBEC) family of proteins, members of which have been shown to post-transcriptionally suppress LINE and SINE retrotransposition. These proteins deaminate cytosine in single-stranded cDNA and at least some of their effect is attributed to this modification of cDNA intermediates. Additional mechanisms of intrinsic immunity have been identified that have anti-retrovirus activity, and some of these may act on retrotransposons as well.

Significance

Effects of Retrotransposons on Genome Structure and Function

In spite of the numerous ways in which retrotransposition can be controlled, retrotransposons have clearly expanded their numbers on an evolutionary timescale, particularly in some complex animal lineages. This might suggest that there has been some advantage to the host organism in retaining retrotransposons and even retrotransposition. What might that be? Some retrotransposons have assumed roles as chromosomal structures. One compelling example is the retrotransposons

clustered in centromeric regions that allow for heterochromatinization of large amounts of DNA so that it can segregate during cell division. A second example is the telomeres in which chromosome extension by retrotransposon TPRT actually substitutes for telomerase in maintenance of chromosome ends. Because retrotransposons move relatively rapidly compared to other genes, they have potential to contribute to speciation through several mechanisms. First, they act to increase the potential of genomes for expansion of gene families and associated acquisition of novel functions. One mechanism of this expansion is reverse transcription of host mRNAs and integration of novel intronless pseudogenes into the genome. Second, the availability of a large pool of repeated sequences allows ectopic recombination between nonhomologous regions of the genome that can cause deletions, inversions, and translocations. Finally, and more directly, differential accumulation of retrotransposons between individuals of a single species can result in activation of transposition when individuals with different transposon content are crossed which in turn can generate sterile progeny, a phenomenon known as hybrid dysgenesis.

Effects of Retrotransposons on Host Gene Expression

Stability of the host–parasite relationships between organisms and their retrotransposons depends upon the ability to regulate retrotransposon expression and activity. Many elements are responsive to signals allowing expression only in specific contexts – mating, stress, or specific developmental windows are a few examples. However, mechanisms for significantly downregulating either most elements or all elements most of the time are present in host cells and it is interesting to speculate that some of these mechanisms have arisen specifically in response to retrotransposon activity. Among the most interesting of these is the ability of cells to sense the presence of repeated sequences and suppress their expression through RNAi. Not surprisingly, expression of retrotransposons can also affect host genes. This can be observed on two levels. First, the physical presence of retrotransposons can have direct effects on expression of associated genes. In the case of LTR retrotransposons, the promoter or terminator sequences in the LTRs can sponsor fortuitous promotion or termination of neighboring gene transcription. Second, however, elements which themselves are targets of inactivation can confer that regulation on neighboring genes causing them to be variably subject to inactivation, a phenomenon referred to as position effect variegation. Additionally, inactivated LTRs can act as insulators, blocking flanking enhancer activity. In a less well-understood example, LINE elements are proposed to have a role in perpetuating spreading of RNA-mediated inactivation of the X chromosome in mammals to confer dosage compensation. Some retrotransposons are differentially expressed in sperm and oocytes and are speculated to be involved in imprinting of associated regions in which genes derived from parental and maternal sources are differentially expressed.

Insertion of elements directly into coding regions is clearly potentially disastrous for gene function. However, because LINEs are relatively poorly transcribed and SINE elements can contain inverted sequences, even insertion into intronic regions can have profound consequences for expression of the

interrupted host gene. Transcription elongation, polyadenylation, alternative splicing, and editing of resulting chimeric transcripts can be affected. However, even this seemingly drastic disruption could have been exploited in higher eukaryotes. Recent experiments have shown that LINE retrotransposition is activated during specific windows of neurogenesis and it is implicated in neuronal plasticity coincident with that period of development.

Repeated sequences including retrotransposons can cause genomic variation via ectopic recombination or retrotransposition. The current activity of both LINEs and SINEs in germline cells means not only that they affect gene expression over evolutionary time frames but that spontaneous insertions can cause heritable disease. There are more than 50 diseases now attributable to retrotransposed elements. The availability of high-throughput sequencing will make it possible to better understand the involvement of these elements in somatic diseases, including cancer, which can result from genetic instability.

Gene Functions Related to Retrotransposons and Retroviruses

An obvious mechanism for retrotransposon modification of host genome-coding potential is reverse transcription and integration of genes to create new copies or pseudogenes that lack introns. These superfluous copies provide genetic raw material for evolution of new gene functions.

The co-evolution of DNA and RNA transposons and retroviruses with their hosts has inevitably resulted in the exaptation of genes from retrotransposon parasites and retroviruses by their hosts. Several gene families have arisen from conservation of the Gag gene. Members of this class in which the nucleocapsid zinc finger is retained are speculated to be transcription factors. The ability of DNA and RNA transposons to recombine DNA has also been co-opted by the cell. Examples include the CENP-B centromeric protein, which interacts with histone deacetylase, and the RAG1 recombinase, which is required to generate immunoglobulin diversity during V(D)J recombination.

Laboratory and Clinical Applications of Retrotransposons

Retrotransposons are sophisticated tools for retrospective and prospective *in vivo* studies. Because of their ability to integrate into and modify genomes, retrotransposons and retroviruses have made unique contributions to phylogenetic analysis and genetic engineering. Retrotransposons move frequently relative to the time frame of speciation; furthermore, the error-prone nature of RT causes a relatively high frequency of changes and can add further resolution to probes of phylogenetic relationships. In more directed approaches, activation of transposition is used to map gene functions. Mutant libraries can be screened for desirable phenotypes and mutant genes readily identified through the retrotransposon tag. If appropriately high levels of retrotransposition can be achieved in organisms with simple genomes, pools of genomic DNA can be sequenced to identify regions that lack insertions and therefore must be essential under the experimental condition. Finally, in cases in which the gene of interest is known, retrotransposons and

retroviruses have proved to provide extremely powerful vectors for introduction of specific test genes into host organisms.

Perspectives

The catalog of retrotransposon sequences is expanding rapidly, accelerated by the advent of high-throughput sequencing of the genomes of diverse species. This has led to new appreciation of the variety of these fascinating elements and the potential impact they have on genomic functions. The very recent discovery of unanticipated mechanisms of gene regulation, such as RNAi, that relate to host control of retrotransposons suggests that many exciting discoveries remain to be made.

Glossary

Calcium Principal second messenger in the control of gene expression by electrical activity in neurons.

CRE-binding protein (CREB) CRE-interacting transcription factor that is a target of cAMP and calcium signaling pathway. Mediates gene induction upon synaptic activity and nuclear calcium transients.

CREB-binding protein (CBP) Transcriptional co-activator regulated by cAMP and calcium signaling pathway; interacts with CREB and many transcription factors thereby conferring calcium and cAMP inducibility.

Cyclic adenosine monophosphate (cAMP) response element (CRE) DNA regulatory element present in the promoter of many genes.

Mitogen-activated protein (MAP) kinases/extracellular signal-regulated kinases (ERK1/2) Important intracellular signaling pathway; activated by electrical activity-induced submembranous calcium signals.

Serum response element (SRE) DNA regulatory element regulated by signaling pathways that are activated by growth factors, serum, or calcium; nuclear target of MAP kinases (ERK1/2) signaling pathway.

Spatial calcium signaling Electrical activity can induce calcium signals in different intracellular compartments; submembranous, cytoplasmic, and nuclear calcium activate gene expression through different mechanisms and have distinct genomic targets.

Neurons initiate many changes in gene expression in response to a synaptic or electrical stimulus. Calcium is the principal second messenger bridging the gap between the synapse and the nucleus. To couple synaptic events to specific genomic responses, neurons exploit the spatial diversity of calcium signals associated with the stimulus. Dendritic calcium signals, activating the mitogen-activated protein (MAP) kinase (extracellular signal-regulated kinase, ERK1/2) signaling cascade, stimulate gene expression mediated by the serum response element (SRE). Calcium signals in the cell nucleus activate the transcription factor cyclic adenosine monophosphate (cAMP) response element (CRE)-binding protein (CREB) and the co-activator CREB-binding protein (CBP). Nuclear calcium may, in particular, initiate and govern gene expression-dependent forms of neuronal adaptations, including acquired neuroprotection and the formation of long-term memory.

Calcium Ions, Key Regulators of Electrical Activity-Dependent Gene Expression

The generation of calcium signals following electrical activation is a fundamental property of neurons that controls many processes in the developing and the adult nervous system. Activity-induced increases in the intracellular calcium concentration result from calcium entering neurons from the extracellular space through ligand and/or voltage-gated ion channels; these calcium transients can be amplified through calcium release from intracellular calcium stores. The *N*-methyl-D-aspartate (NMDA) receptor, a calcium permeable, glutamate-gated ion channel, plays a particularly important role in the mammalian central nervous system. Calcium entry through NMDA receptors, triggered by electrical activity, stimulates mechanisms that affect synaptic connectivity and neuronal network behavior leading to

information storage; NMDA receptor-mediated calcium entry can also promote neuronal survival or cause cell death. Important for the consolidation of these activity-induced responses is that calcium signals, generated initially at the plasma membrane, are transduced to the cell nucleus where they stimulate the expression of particular genes. Thus, neurons use calcium ions to couple electrical signals to specific genomic events. Among the target genes of calcium signaling are neurotrophic factors, cytoskeletal proteins, and transcription factors (see below).

Spatial Calcium Signaling in Synapse-to-Nucleus Communication

The use of calcium as a universal signal mediator raises the issue of specificity: what mechanism allows neurons to use a single second messenger to convert a diverse range of electrical stimuli into distinct gene expression responses? Neurons appear to achieve this by using a calcium code: a given electrical stimulus is transformed into a calcium signal with particular spatial and temporal properties. Thus, an activity-induced neuronal calcium signal is a signature of the stimulus; it functions as its intracellular representation and links the stimulus to a gene expression response. The amplitude and the duration of the calcium signal, two features that transcriptional regulators decode, primarily control the magnitude of the increase in transcription. The site of calcium entry also matters; indeed, calcium entry through synaptic NMDA receptors and through extrasynaptic NMDA receptors has opposing effects on the activation of a crucial transcription factor (see below). However, most importantly, the genomic response depends on which part of the neuron is invaded by the calcium transient (Figure 1). For example, a weak synaptic input may generate a calcium signal that is confined to the submembranous space in

Figure 1 Schematic drawing of a neuron and the intracellular signaling pathways that mediate the induction of gene expression following neuronal activity. Three spatially distinct calcium signals (submembranous, cytoplasmic, and nuclear) are illustrated. Each type of calcium signal couples to a specific effector mechanism with distinct genomic targets. The decoding, by transcriptional regulators, of spatial information contained in activity-induced calcium transients allows neuronal impulse patterns to specify gene expression responses.

the immediate vicinity of the site of calcium entry; following a stronger stimulus, calcium increases may reach further into the dendritic tree. Under certain conditions, the calcium signal can invade the cell body and the nucleus. It is important for the specification of the gene expression response exactly which subcellular compartment (i.e., submembranous space, dendritic tree and somatic cytoplasm, and cell nucleus) undergoes a change in the calcium concentration. Thus, the ‘dialog between genes and synapses’ (to use a phrase from Eric Kandel) exploits the spatial and temporal diversity of calcium transients associated with electrical activation. Transcriptional regulation and the neuronal responses depend on how calcium enters the neurons, the amplitude of the signal, how long the signal lasts, and what subcellular compartment it invades.

Regulators of Calcium-Induced Gene Expression

Much knowledge of the mechanisms of electrical activity-dependent gene expression comes from studies of the *c-fos* gene. This gene is induced, without the need for new protein synthesis, within minutes after the stimulation. The *c-fos* gene encodes a DNA-binding protein; together with members of the Jun transcription factor family it forms the AP-1 complex that is involved in the regulation of many genes. *c-fos* was the first gene found to be induced by membrane depolarization and calcium influx into excitable cell lines and primary neurons.

SRE and CRE

Analysis of the *c-fos* promoter revealed that calcium influx-induced gene transcription is mediated by two distinct DNA

regulatory elements: the CRE and the SRE. The CRE and the SRE were previously known to mediate gene induction upon increasing intracellular levels of cAMP or following the addition of serum to serum-starved fibroblasts, respectively. Analysis of calcium regulation of SRE-dependent and CRE-dependent transcription uncovered the importance of the intracellular localization of the calcium signal: an increase in cytoplasmic calcium activates gene expression mediated by the SRE; by contrast, activation of the CRE and the CREB require increases in the nuclear calcium concentration (see below). Thus, a single second messenger can, depending on its intracellular localization, induce distinct responses.

NFAT and DREAM

Calcium-responsive regulators of transcription, other than the SRE and CREB, include the nuclear factor of activated T-cells (NFAT) and the downstream regulatory element (DRE)-binding protein, DREAM (DRE-antagonist modulator). NFAT is important in the immune system; it mediates in activated T-cells the induction of interleukin 2 expression, a critical step in the response to antigen stimulation. DREAM is a multifunctional calcium-binding protein that can act as a repressor of gene transcription. The importance of spatial calcium signaling in the regulation of the SRE, the CRE, NFAT, and DREAM is outlined in the following section.

Calcium Signals in Different Subcellular Compartments

Calcium brings about biological responses through activating effector molecules such as protein kinases or protein

phosphatases. Exactly which calcium-regulated molecule is stimulated depends on the subcellular localization of the calcium transient.

Submembranous Calcium Signals

A calcium microdomain restricted to the submembranous space near synaptic NMDA receptors serves as the on-switch of the MAP kinase (ERK1/2) cascade following synaptic activity. This signaling pathway is a major route for intracellular communication. The actions of MAP kinases (ERK1/2), both in the vicinity of calcium entry sites and in the nucleus, are involved in controlling many different brain functions ranging from learning to neuronal survival and light-induced shifts in the circadian rhythm.

One important target of the MAP kinase (ERK1/2) cascade is the nucleus. The MAP kinase (ERK1/2) signal propagates to the nucleus independently of global (i.e., cell-wide) increases in the calcium concentration and stimulates gene expression mediated by the SRE. It can also lead to the phosphorylation of CREB on its activator site, serine 133. Although this phosphorylation is necessary for inducing CREB-mediated transcription it is not sufficient; a second regulatory event is required that involves stimulation of the activity of the CREB coactivator CBP by nuclear calcium and nuclear calcium/calmodulin (CaM)-dependent protein kinases (see below). Nevertheless, the MAP kinase (ERK1/2) cascade acts as an auxiliary pathway that promotes at least one of several activating steps that control CREB-dependent gene expression. CREB target genes include *c-fos* and the brain-derived neurotrophic factor (BDNF) (see below).

Dendritic/Cytoplasmic Calcium Signals

The second calcium pool with a role in transcription regulation by neuronal activity is localized to the dendrites and the cytoplasm of the cell body. One of the targets of dendritic/cytoplasmic calcium is calcineurin (CaN). CaN is a cytoplasmic serine/threonine phosphatase that, upon activation by calcium/CaM, catalyzes the dephosphorylation of NFAT which unmasks an NFAT nuclear localization signal. The activated CaN/NFAT complex is subsequently imported into the nucleus to activate gene transcription. Possible target genes of the CaN/NFAT-signaling module are genes involved in regulating calcium homeostasis; this includes the IP₃ receptor and plasma membrane calcium adenosine triphosphatases (ATPases) (calcium pumps).

Once calcium concentrations have returned to basal levels, the NFAT/CaN complex dissociates, NFAT is exported from the nucleus and transcription is rapidly shut off. Thus, the magnitude of the transcriptional response is a function of the duration of the calcium signal; only prolonged increases in intracellular calcium efficiently activate NFAT-mediated gene expression. In addition, increases in nuclear calcium are required to maintain NFAT in the nucleus and to sustain transcription. Such calcium signals (i.e., elevated calcium plateaus in the cytoplasm and the nucleus) are typically seen in antigen-stimulated T-cells that require NFAT activation for the immune response (see above). In neurons, synaptic activity often generates only transient increases in intracellular calcium that may induce a less robust NFAT activation.

Nuclear Calcium Signals

The third player in electrical activity-dependent gene expression is nuclear calcium. Synaptically evoked calcium transients can be amplified by calcium release from intracellular stores and are propagated, possibly in the form of a regenerative wave, to the nucleus. Nuclear calcium is a central regulator of neuronal gene expression. It activates nuclear calcium/CaM-dependent protein kinases and is the principal regulator of gene expression by the CREB/CBP complex. Activation of gene expression by CREB/CBP requires at least two regulatory events: phosphorylation of CREB on its activator site serine 133, which allows CBP to be recruited to CREB. The second event is the stimulation of CBP activity. The first regulatory step can be catalyzed by several protein kinases, including kinases of the MAP kinase (ERK1/2) signaling pathway (triggered by submembranous calcium; see above) and nuclear calcium-induced CaM kinases. Induction of CBP activity, however, depends upon increases in the nuclear calcium concentration and the activation of nuclear CaM kinases.

The only other second messenger known to stimulate CBP activity and to increase CREB/CBP-mediated gene expression is cAMP. Global increases in the intracellular concentration of cAMP stimulate the cAMP-dependent protein kinase (PKA); upon binding of cAMP to the PKA regulatory subunit, the catalytic subunit of PKA translocates to the cell nucleus to activate the CREB/CBP complex. A large body of literature suggests that cAMP and PKA are important for certain long-term, gene expression-dependent forms of plasticity and learning in *Aplysia californica* and *Drosophila melanogaster*. Mammalian neurons are also capable of increasing intracellular levels of cAMP following synaptic activity through a process that involves calcium/CaM-dependent adenylyl cyclases. However, electrical activity does not appear to elevate global levels of cAMP sufficiently high to stimulate the CREB/CBP complex, although it may increase cAMP and PKA activity locally leading to the phosphorylation of neurotransmitter receptors or other proteins in the postsynaptic space. Thus, the cAMP-PKA system may be important for localized dendritic signaling in the mammalian nervous system, but the stimulation of CREB/CBP-dependent gene expression following synaptic activity appears to be controlled by nuclear calcium signals.

CBP is a coactivator of CREB but it also interacts with several other DNA-binding proteins thereby conferring calcium inducibility. One example is the transcription factor c-Jun that can function as a calcium-regulated activator. Thus, control of CBP activity by nuclear calcium and nuclear CaM kinases provides a general mechanism through which electrical activity regulates an entire class of transcription factors and, consequently, many genes. The generation of nuclear calcium transients activating CBP-containing complexes is likely to be important for activity- and gene transcription-dependent forms of neuronal adaptation including acquired neuroprotection, information storage, and memory formation. A transcriptome study revealed that in mouse hippocampal neurons, nuclear calcium is one of the most potent signals in neuronal gene expression. The induction or repression of nearly 200 activity-regulated genes is dependent upon nuclear calcium signaling. The nuclear calcium-regulated gene pool contains several genes that can provide neurons with a robust

neuroprotective shield and renders them more resistant to cellular stress and toxic insults. In line with the concept that most (perhaps all) activity-regulated, persistent adaptations require that stimulus-associated calcium signals invade the cell nucleus is the observation that nuclear calcium signaling is critical for the formation of long-term memory in *D. melanogaster* and in mice.

A second type of transcriptional regulation by nuclear calcium involves DREAM. Rather than being controlled by calcium/CaM-dependent enzymes, the ability of DREAM to modulate transcription is directly controlled by nuclear calcium. DREAM is a calcium-binding protein that, in the absence of calcium, interacts with the DRE and represses transcription. Increases in nuclear calcium lead to the formation of a calcium/DREAM complex; calcium-bound DREAM dissociates from the DNA allowing transcription to take place. Potential DREAM-binding sites are present in many different genes; the involvement of DREAM is best documented for the prodynorphin gene.

CREB Shut-Off Pathway

The genomic responses (and their effects on survival and plasticity programs) induced by calcium flux through synaptic NMDA receptors are antagonized by a signaling pathway stimulated by the addition of glutamate to extracellular medium. Bath glutamate application stimulates both synaptic and extrasynaptic NMDA receptors as well as other types of glutamate receptors. Pharmacological experiments revealed that calcium flux through extrasynaptic NMDA receptors is responsible for this nuclear signaling mechanism that negatively regulates gene expression; this pathway is also coupled to neuronal cell death. The target transcription factor inactivated following calcium entry through extrasynaptic NMDA receptors entry is CREB; the CREB shut-off is brought about by a rapid dephosphorylation of CREB on its activator site, serine 133 (Figure 2).

Extrasynaptic NMDA Receptors Antagonize Nuclear Calcium Signaling and BDNF Gene Expression

After calcium entry through extrasynaptic NMDA receptors, one of the consequences of the CREB shut-off is the suppression of BDNF gene expression. BDNF, a neurotrophic factor, activates intracellular signaling pathways through binding to TrkB, a receptor tyrosine kinase; BDNF also acts as a fast neurotransmitter and can rapidly depolarize neurons. BDNF has many functions in neuronal plasticity and cell survival. BDNF gene transcription is electrical activity dependent and controlled, antagonistically, by two calcium-signaling pathways: calcium flux through synaptic NMDA receptors (or through L-type voltage-gated calcium channels) stimulates BDNF gene transcription; by contrast, calcium flux through extrasynaptic NMDA receptors antagonizes increases in BDNF expression. The BDNF gene's promoter is complex and provides binding sites for many transcription factors; however, a key factor is CREB, which may explain the opposing action of synaptic and

Figure 2 Schematic illustration of the role of synaptic and extrasynaptic NMDA receptors in neuronal gene expression, plasticity, survival, and cell death.

extrasynaptic NMDA receptors on influencing BDNF gene transcription. Activation of synaptic NMDA receptors (or L-type voltage-gated calcium channels) strongly promotes CREB activity, whereas CREB function is shut-off following activation of extrasynaptic NMDA receptors; those receptors trigger a CREB shut-off signal and antagonize increases in BDNF transcription induced by calcium entry through synaptic NMDA receptors. This underscores the importance of the intracellular localization of the calcium signal for the specification of the neuronal response.

Glossary

Cajal bodies Spherical nuclear bodies (1–5/nucleus) enriched in messenger RNA (mRNA), ribosomal RNA (rRNA), and small nuclear RNA (snRNA) processing factors.

Nuclear compartment A nonmembrane-bound subnuclear structure in which a variety of factors accumulate to facilitate specific nuclear processes.

Nucleus A membrane-bound cellular structure containing DNA which controls the cell's growth, metabolism, and replication.

PML nuclear bodies Spherical nuclear structures (10–30/nucleus) rich in a variety of factors, many of which are involved in transcription regulation.

SC35 domains Twenty to forty irregular speckles in the nucleus in which numerous factors required for mRNA metabolism accumulate.

Survival of motor neuron (SMN) gems Nuclear bodies enriched in SMN protein and other factors involved in small nuclear ribonucleoproteins (snRNP) assembly. Gems often associate or coincide with Cajal bodies.

Introduction

The orchestrated expression of the genome's ~35 000 genes is largely regulated by epigenetic changes to chromatin and nuclear structure, involving the formation of more dense largely inactive heterochromatin versus more open and more expressed euchromatin. In somatic cells, the genome is packaged at a higher level into large, cytologically visible domains of euchromatin and repressive heterochromatin, which tend to occupy different regions of the nucleus. Euchromatin occupies the more internal nucleoplasm, and this large euchromatic compartment is further partitioned into several nonchromatin subcompartments enriched in different RNA metabolic and regulatory factors. By contrast, heterochromatin forms a compartment of compact DNA at the nuclear periphery, where many inactive sequences have been localized in mammalian cells.

Although it is beyond the scope of this article, it should be noted that our lab and several others have studied the organization of individual genes with distinct nuclear domains, using fluorescence *in situ* hybridization (FISH) methods to visualize single genes and their nuclear RNAs. In sum, evidence indicates that nuclear localization of specific genes with distinct nuclear compartments contributes to their regulation and/or efficient expression of RNAs, but this alone does not determine the expression status of a gene. For example, some active genes are at the nuclear periphery near heterochromatin, whereas some inactive genes will be in the more euchromatic regions of the nucleoplasm. Nonetheless, an important theme in nuclear structure is that the organization of specific genomic loci is clearly nonrandom with respect to many of the nuclear compartments described below. This article focuses on summarizing the main features of these various nuclear substructures themselves, beginning with the nuclear periphery and heterochromatic compartment and then the various domains and bodies throughout the large internal euchromatic compartment.

The Nuclear Periphery

The Nuclear Envelope and Lamina

The cell nucleus is bounded by a bilayered nuclear envelope (NE) that separates the nucleus from the cytoplasm. This

structure is comprised of the inner and outer membranes and the nuclear pores, which allow communication between the nucleus and the rest of the cell. Internal to the NE is a filamentous layer, the lamina. Several lamin proteins form the lamina which encircles the nuclear periphery at the interface between chromatin and the inner nuclear membrane (Figure 1), but lamins are also found more dispersed throughout the nucleoplasm. Lamins are required for transcription and DNA replication and are encoded by three separate genes, lamin B1, B2, and A/C, which produce several alternatively spliced isoforms. The lamina contains numerous factors that interact with the lamins, including emerin, lamin B receptor (LBR), and lamina associated peptides (LAPs) 1 and 2, all of which also associate with chromatin. Via these chromatin interactions, the NE and lamina serve as an anchoring structure for nuclear architecture, positioning chromosome territories in interphase.

Peripheral Heterochromatic Compartment

The prevalence of heterochromatin formation in genome regulation is manifest cytologically, generating cell-type specific architectural arrangements of a prominent nuclear heterochromatic compartment. Discrete regions of densely packaged heterochromatin are typically compressed at the nuclear and nucleolar periphery (Figure 2), and also are present in smaller nucleoplasmic blocks, in cell-type specific patterns. Constitutive heterochromatin is comprised of DNA that is rich in repetitive sequences, such as centromeric satellites, whereas facultative heterochromatin consists of sequences that are euchromatic in some cell types. Heterochromatin is typically late replicating (Figure 2) and most often has certain biochemical features, such as deacetylation on histone H4 and methylation on histone H3, as well as increased DNA methylation. Although not all inactive genes localize in a heterochromatic compartment, inactive genes and certain chromosomes tend to reside at the periphery in certain cell types. Inactivation of one X chromosome in mammalian females is a pre-eminent example of heterochromatin formation, controlled by the large noncoding X (inactive)-specific transcript (XIST) RNA, which coats and induces silencing of the X chromosome, positioning

Figure 1 Lamin B1 staining (red) illuminates the nuclear lamina which encircles the nuclear DNA. The nucleus is stained blue using the DNA stain 4',6-diamidino-2-phenylindole (DAPI).

Figure 2 Incorporation of BrdU (green) into late replicating DNA delineates the peripheral heterochromatin that abuts the nuclear lamina.

it in the heterochromatic compartment at the nuclear or nucleolar periphery.

Chromosome Territories and Transcription Factories

With the development of FISH techniques, it became possible to visualize the distribution of DNA from an individual chromosome in interphase nuclei. This revealed that, despite the lower condensation of most interphase DNA, the interphase chromosome occupies a discretely bordered territory within nuclear structure (Figure 3). Thus, the DNA of one chromosome is not substantially intermingled with that of other chromosomes, although there may be some interconnections in the outer region of each territory. Although each chromosome occupies a distinct territory, there is no clearly visible space (devoid of chromatin or other ultra-structures) that defines the border of these territories; thus, they are only apparent by hybridization of a DNA library from a specific chromosome.

Several labs have investigated whether chromosome territories are organized in a specific three-dimensional (3D) position or in a particular order. Although in some specialized cells of certain species this appears to be the case, in mammalian cells there are preferred regions for specific chromosomes, but generally not a precise order of specific 3D coordinates. For example, larger chromosomes and less gene-dense chromosomes tend to be closer to the nuclear periphery, whereas smaller and more gene-rich chromosomes tend to be more central (including ribosomal (rDNA) bearing chromosomes that are with nucleoli). Another major question that has been investigated concerns the organization of genes within each chromosome territory. Several studies indicate that canonical

Figure 3 Fluorescence hybridization with a library of DNA from an individual chromosome defines an interphase chromosome territory for each of the two homologous chromosomes.

protein-coding genes have a propensity to reside in the outer $\sim 1/3$ of the chromosome territory. Whether the position of genes in the territory changes with their activity has been a subject of some debate, it appears that certain highly active gene clusters may loop out away from their territory upon activation, but this is not seen for most genes studied, as many show no clear difference in position within the territory relative to activity. Interestingly, on the inactive X chromosome, genes studied to date position at the very outer border of the chromosome territory, largely outside the dense heterochromatic core of the chromosome (the Barr Body). This suggests that this condensed, inactive chromosome makes more sharply defined an underlying organization that may be present on all chromosomes, with loose compartmentalization of coding genes peripheral to a core of noncoding more repeat-rich DNA.

Transcription factories are smaller structures within nuclei that are generally defined by the punctuate distribution of RNA polymerase II into approximately 1000–2000 very small discrete foci in most cells which is just within the limits of resolution of light microscopy. These transcription foci may be more prevalent near the peripheral zone of chromosome territories, near splicing factor-rich SC35 domains or other regions of high activity. While it is not entirely clear if these $0.1 \mu\text{m}$ foci represent a distinct structural compartment, a few studies have raised the possibility that coordinately regulated genes can cluster at these foci.

The Nucleolus

The nucleolus is the best-known subcompartment of euchromatin, as it was long ago easily visualized by phase microscopy and has long been known to be the site of highly active ribosomal RNA (rRNA) synthesis. In fact, while it was not widely appreciated initially, the nucleolus established the precedent for the compartmentalization of genes and RNA metabolic factors into an organized structure devoted to a certain function: a ribosomal subunit factory. The rDNA genes that form the nucleolus are on 10 different human chromosomes, and although the number and arrangement of nucleoli differ in cell-type specific patterns, in all cases genes on separate chromosomes must congregate within these structures for this common purpose. Ribosomal genes and RNA are transcribed

Figure 4 The nucleolus is typically visible as a dark region of low DNA density by DAPI DNA stain, due to the abundance of ribosomal RNA and proteins assembling throughout most of the nucleolus.

in small regions of the nucleolus known as the 'fibrillar center (FC)' and 'dense fibrillar component (DFC)'. The bulk of the nucleolus is the granular component (GC), where rRNA and proteins assemble to the ribosomal subunit (Figure 4). In addition to its well-established importance in the efficient production of rRNAs and ribosome assembly, evidence indicates that the nucleolus likely has expanded functions related to RNA metabolism or possibly even heterochromatin formation, and thus the nucleolus is increasingly considered a multi-functional nuclear suborganelle.

Splicing Factor Compartments, Speckles, or SC35 Domains

In the eukaryotic nucleus, the distribution of pre-messenger RNA (mRNA) splicing factors is not uniform, but is markedly concentrated at 15–30 sites, with lower levels of factors diffused throughout the nucleoplasm (Figure 5). Various referred to as 'speckles', 'SC35 domains', or 'splicing factor compartments (SFCs)', these irregular but discrete domains are most frequently visualized with an antibody directed against the spliceosome assembly factor SC35. Each domain, 0.5–3.0 μm in diameter, corresponds largely, if not entirely, to ultrastructures termed 'interchromatin granule clusters (IGCs)'. In addition to spliceosome assembly factor SC35, these domains contain numerous splicing factors and SR proteins, as well as poly(A) RNA, poly(A) RNA-binding protein, several factors implicated in RNA export and in some studies RNA polymerase II and lamins. Recently, it has been shown that nuclear paraspeckle assembly transcript 2 (NEAT2) RNA, one of the most abundant noncoding RNAs in the nucleus, also is markedly enriched in SC35 speckles. In addition, all of these components are more diffusely distributed throughout the nucleus. Although the positions of the domains themselves are relatively immobile, they are dynamic structures in that factors within them are in rapid flux dependent upon their phosphorylation state. It is likely that ~100 different proteins involved in pre-mRNA metabolism localize, at least transiently, to these domains.

Because the IGCs show less label with uridine incorporation, it had been thought that these regions would not contain mRNA or pre-mRNA but might be just storage sites unassociated with active genes. However, many (about half) of the active genes studied have been shown to position directly at

Figure 5 Splicing factor rich SC35 domains as visualized in a human fibroblast nucleus immunostained for the spliceosome assembly factor SC35 (red).

the periphery of SC-35 domains, and RNAs from highly expressed genes have been found within them. The organization of these genes with domains is locus-specific and cell-type-specific. Evidence now suggests that most, if not all, splicing factor domains associate with numerous genes and may contain mRNAs derived from them, but they may simultaneously serve as reservoirs or reassembly sites of RNA metabolic factors. The placement of specific genes near these concentrated domains of RNA metabolic factors suggests a specific nuclear organization of the gene relative to the domain which would facilitate the rapid reassembly and use of large RNA metabolic complexes for highly expressed and complex genes (Figure 6).

Paraspeckles

Paraspeckles were so named due to their close juxtaposition to the larger SC-35-rich speckles (Figure 7). Paraspeckles number between about 5 and 15 per cell. While they are present in mammalian somatic cells, similar to SC35 domains, they are not found in human embryonic stem cells. Paraspeckles, 0.5–1.0 μm in size, were initially identified due to their concentration of certain proteins implicated in RNA editing, including PSP1, PSF, and p54/NONO. While these proteins are also present at lower levels throughout the nucleoplasm, it was later shown that NEAT1 long-noncoding RNA is exclusively localized to paraspeckles, and it provides the structural underpinnings, setting a precedent for an architectural role for noncoding RNA in forming a cytological scale nuclear sub-compartment. While the function(s) of paraspeckles is being investigated, there is evidence that they are involved in adenosine-inosine editing of RNAs and in the nuclear retention of mRNAs for which the nuclear export is regulated in relation to cell signals.

Promyelocytic Leukemia Nuclear Bodies, ND10

Mammalian nuclei contain on the order of 10 spherical structures termed 'promyelocytic leukemia (PML) nuclear bodies' (PML NBs) (also termed PODs, ND10, or Kremer bodies) (Figure 8). These 0.2–1 μm bodies were first observed by electron microscopy (EM) and later found to contain the PML

Figure 6 SC35 domain model. Domains may function by coupling the completion of mRNA maturation and release for mRNA export with the recycling/preassembly of factor complexes. Because the RNA metabolic machinery requires interaction of a large number of different factors, their concentration at a site would facilitate recycling and rapid reuse for expression by adjacent genes. Adapted from Johnson CV, Primorac D, McKinstry M, et al. (2000) Tracking COL1A1 RNA in osteogenesis imperfecta. Splice-defective transcripts initiate transport from the gene but are retained within the SC35 domain. *Journal of Cell Biology* 150: 417–431, and Hall LL, Smith KP, Byron M, and Lawrence JB (2006) Molecular anatomy of a speckle. *The Anatomical Record Part A* 288: 664–675.

Figure 7 Paraspeckles are marked by their concentration of NEAT1 RNA (red) and are smaller structures that typically lie adjacent to SC35 domains, which are illuminated here by their enrichment for NEAT2 RNA (green).

protein. Interest in this nuclear body, and nuclear structure in general, significantly increased with the discovery that the gene-encoding PML is fused to the retinoic acid receptor gene in the t(15;17) translocation of acute promyelocytic leukemia (APL). The resulting PML-retinoic acid receptor fusion protein causes a breakdown of PML domains, a major hallmark of APL. PML bodies are also targeted by many DNA viruses in early infection, and are the site of viral transcription initiation. Subsequently, the viral early proteins localize to and eventually disrupt PML NBs. The number and size of PML NBs is also regulated by interferons and cellular stress, such as oxidative stress and DNA damage. In addition to the classical round PML NBs, recent studies have noted highly unusual PML structures in human embryonic stem cells.

The lynchpin of the PML NB is the PML protein, essential for PML body formation. The PML protein contains a RING finger, B-box coiled-coil (RBCC) motif that allows PML to interact with many proteins. The PML protein itself is involved in antiviral defense by impairing viral replication, inhibiting

Figure 8 PML nuclear bodies. Human fibroblast nucleus stained with DAPI (blue) has numerous PML nuclear bodies visualized with an anti-PML antibody (red).

synthesis of viral mRNAs or by inducing apoptosis in infected cells. Although it does not appear that these antiviral activities occur in the PML NB, many viruses target disruption of the PML NB as a means of evading the cell's defense mechanisms.

The myriad PML NB proteins are involved in a number of different cellular processes, including tumor suppression, cell-cycle control, DNA repair, senescence, apoptosis, immune response, and transcription regulation. A few of the over 160 proteins which concentrate within PML NBs, such as Sp100 and death-associated dead protein (Daxx)1, are present under all conditions, but many others localize under certain conditions, in addition to lower levels in the nucleoplasm. Some proteins do not colocalize with all PML NBs or in all cell types, suggesting that different PML NBs may have distinct functions.

The sheer variety of proteins found in PML bodies has made attribution of a single function almost impossible. One theory is that PML NBs are nuclear depots from which proteins are recruited in response to stimuli such as viral attack or other cell stress. PML NBs could also be sites for degradation of some nuclear proteins, or act as a platform for posttranslational modifications such as phosphorylation, acetylation, and SUMOylation. In fact, over 40% of the factors found in PML NBs are SUMOylated, and small ubiquitin-like modifier (SUMO)-specific ligases and proteases have been detected in these bodies, suggesting that PML NBs may be SUMOylation hot spots. PML has been found to affect the activity of some stem cell related factors via posttranslational modification and, thus, may have a role in stem cell self-renewal.

Given their potential to sequester or modify transcription factors, it has been proposed that PML NBs affect chromatin architecture and transcription regulation.

Cajal (Coiled) Bodies, Histone Locus Bodies, and Gems

Cajal Bodies

First described in 1903 as nucleolar accessory bodies, the Cajal (coiled) bodies (CBs) are usually seen as roughly spherical 0.1–2.0 μm structures numbering one to five per nucleus (see [Figure 9\(a\)](#)), varying in number and size during the cell cycle and in different cell types. The Cajal bodies are not seen in all

Figure 9 Cajal bodies, seen using an anti-coilin antibody (red) can appear as round nucleoplasmic bodies in highly proliferative cultured cells like the cervical carcinoma cell HeLa (a) or can be found to cap the nucleolus in a tissue section of mouse brain neurons (b). DNA in nuclei is stained with DAPI.

cells or tissues, but are especially prominent in highly proliferative cells such as cancer cells or metabolically active cells like neurons. The neuronal CBs, as originally identified, are not round nucleoplasmic bodies, but are found capping the nucleolus as seen in **Figure 9(b)**. This localization illustrates the close association between the nucleolus and the CBs. Whether the CBs capping the nucleolus are functionally distinct from the nucleoplasmic bodies most often seen in cultured cells is unknown.

The coilin protein was first identified using human auto-immune serum and has become the marker most often used to visualize CBs. Although relatively little is known about the function of coilin, studies have indicated that it is the link between CBs and the nucleolus. In addition to coilin, numerous small nuclear RNAs (snRNAs) and proteins of both nuclear and nucleolar origin are enriched in the CBs. These include factors involved in ribonucleoprotein maturation, RNA polymerase assembly, spliceosome assembly, and telomere elongation.

CBs have been shown to spatially associate with specific gene loci in the nucleus. They associate with several U snRNA gene loci (U1, U2, U4, U11, and U12) in a manner suggesting that CBs could have relationship to expression and nuclear metabolism of these snRNAs. The CBs also contain pre-U2RNA, implicating them in snRNA modification or export. In addition, Cajal bodies contain small Cajal body-specific RNAs (scaRNAs) which catalyze the methylation and pseudouridylation of snRNAs after the assembled small nuclear ribonucleoproteins (snRNPs) are transported into the nucleus. Cajal bodies also contain the core telomerase components and can transiently associate with telomeres in S phase of the cell cycle, suggesting a possible link to telomere elongation.

Survival of Motor Neuron Gems in Relation to CBs

Modification of snRNAs is likely not the sole function of CBs. The disease spinal muscular atrophy results from deletion of a gene encoding the survival of motor neuron (SMN) protein. This protein is consistently enriched in foci termed 'SMN gemini of Cajal bodies (gems)', since in the cell line in which they were discovered, gems were often very closely associated or even coincident with CBs (see **Figure 10(a)**). However, subsequently in many cultured cells studied, SMN and coilin

Figure 10 SMN gems are associated with CBs. By dual staining with anti-SMN antibody (red) and anti-coilin antibody (green), we see that SMN gems are separate from, but often associated with, CBs in some cells such as HeLa (a), but are most often found to be completely coincident with CBs (arrows) as seen in the breast cancer cell HCC1937 (b). Nuclei are stained with DAPI.

staining appear coincident in CBs (**Figure 10(b)**), so SMN is generally thought of as a component of CBs and gems are not distinct nuclear bodies. At a molecular level, SMN protein complexes with a number of other factors in a structure referred to as an 'assemblysome'. SMN accompanies newly assembled snRNPs back into the nucleus, but it is not clear if this process is related to their localization in CBs. However, this role for SMN is consistent with the idea that CBs may be involved in the recycling and/or biogenesis of splicing factors. An extension of this hypothesis is that CBs are sites of preassembly of pols I, II, and III transcription/RNA processing complexes or transcriptosomes.

Histone locus bodies

Once thought to be CBs, histone locus bodies (HLB) have been found to be related but distinct subnuclear structures. HLBs are spatially associated with the histone gene clusters on chromosomes 1 and 6. Although HLBs contain concentrations of many factors also found in CBs, such as coilin, they also have several unique factors, many of which are involved in histone mRNA processing. Among these are U7snRNA, the U7 snRNPs Lsm10 and Lsm11, stem-loop-binding protein (SLBP), FADD-like IL-1 β -converting enzyme (FLICE)-associated huge protein

(FLASH), nuclear protein, ataxia telangiectasia (NPAT), negative elongation factor, and simplekyn. Although the function of HLBs is unclear, their components and localization suggest that they may be sites of histone mRNA processing.

Conclusion

While this article has focused on some of the most-studied non-nucleolar compartments of mammalian nuclear structure, nuclear subdomains are still being discovered, and there is already evidence for the existence of multiple other compartments about which less is known. These include the perinucleolar compartment (PNC), Sam68 bodies, cleavage bodies, polycomb bodies, and Oct1/PTF/transcription (OPT) domains. Some of these structures (PNC) are hallmarks of cancer cells. While the nuclear compartments described here all have different components and are implicated in distinct functions, a common theme is that these compartments serve to concentrate and sort factors and RNAs involved in similar processes, presumably to enhance the efficiency and/or regulation of those processes within the nucleus. While in most cases, proteins that concentrate in a particular domain or body are also present at low levels in other regions of the nucleoplasm, the concentration of numerous factors involved in the same aspect of gene expression or particular type of RNA metabolism will facilitate the formation of large, complex macromolecular structures. Alternatively, in some cases, the concentration at a particular site may serve as a means to sequester factors away from interactions with other factors or specific areas of the genome. While these various compartments comprise relative stable nuclear structures, often the factors within these structures are dynamic, showing rapid movements within or between nuclear compartments. In addition, these various domains and bodies may change in number, shape, or specific components during the cell cycle and different cellular states, including tissue-type differentiation. Essentially all of these nuclear compartments disassemble and reassemble during mitosis. The consideration of how specific gene loci may associate with or be impacted by particular structures is important and complex, but it is clear that the organization of the genome is intimately integrated with at least some of these nuclear non-chromatin compartments. Finally, it is interesting to note that some bodies and domains appear to interact frequently with each other, such as the association of PML bodies, CBs, splicing factor (SC-35) speckles, and paraspeckles. The diversity of subcompartments within nuclear structure makes clear that the bland, homogeneous vision of the interphase nucleus that persisted for many decades is now firmly dispelled. The interphase nucleus reflects the functional organization of the genome associated with a multitude of subcompartments each of which is implicated in

efficient expression or regulation of one or more of the myriad functions of cell nuclei.

Glossary

Apoptosis A programmed cell death pathway that is used by an organism to eliminate unwanted cells or to maintain organ size.

Cytokines Factors that regulate the growth and activity of blood cells and lymphocytes.

Proteasome A cellular complex composed of several proteases that degrade ubiquitinated proteins.

Protein kinase An enzyme that can add a phosphate group onto specific residues in a target protein, which then affects the activity of the target protein.

Signal transduction A molecular process by which a signal (often an extracellular compound) effects a cellular response. This is usually a multicomponent step-wise

intracellular pathway that is initiated by binding of an extracellular ligand to a cell-surface receptor, which sets into motion a cascade of cytoplasmic protein–protein interactions and enzymatic activities that ultimately lead to the activation of a transcription factor which then regulates the expression of a biologically relevant set of target genes.

Transcription factor A protein or protein complex that binds to specific DNA sequences to regulate (increase or decrease) the rate of transcription of a gene.

Ubiquitin A small (~8.6 kDa) polypeptide chain that can be conjugated to substrate proteins, which often targets them for degradation by the proteasome or serves as a posttranslational modification to regulate protein activity.

Introduction

Nuclear factor kappa B (NF κ B) is a family of structurally related DNA-binding proteins that act as transcription factors to regulate the expression of a wide variety of genes involved in many key cellular and organismal processes. The discovery of mammalian NF κ B is generally attributed to Ranjan Sen and David Baltimore, who were studying the regulation of expression of a specific immunoglobulin gene; however, it is now clear that earlier researchers studying an avian retroviral oncoprotein (v-Rel) and a protein (Dorsal) required for the establishment of *Drosophila* embryonic polarity were also studying NF κ B activity. This article focuses primarily on the mammalian NF κ B system, although most of the discussion is also applicable to the NF κ B system in other vertebrates and invertebrates. NF κ B activity is controlled by a multi-component signal transduction pathway: that is, in most cells NF κ B is inactive in the cytoplasm until one of many inducers initiates the signal transduction pathway that ultimately converts an inactive form of NF κ B into an active nuclear DNA-binding protein. Misregulation of NF κ B activity has been implicated in a number of human diseases, including several chronic inflammatory diseases and cancer, and the NF κ B pathway is used by several viruses as part of their pathology or replication. As such, the NF κ B pathway is the subject of intense focus for pharmacological intervention.

NF κ B Proteins and Protein Structure

The NF κ B transcription factor family is comprised of several evolutionarily conserved proteins that are related through a protein domain, usually called the 'Rel homology domain (RHD)', which has sequences required for DNA binding, dimerization, and nuclear localization (Figure 1(a)). In simple marine organisms, such as sea anemones, corals, and sponges,

there is a single NF κ B protein, while in *Drosophila*, there are three NF κ B proteins (Dorsal, Dif, and Relish). In vertebrates, the NF κ B protein family is comprised of five proteins: p50/p105, p52/p100, c-Rel, RelA (also called p65), and RelB. There is also an avian retroviral oncoprotein, v-Rel, which is a member of this family.

All NF κ B proteins contain the ~300-amino-acid RHD toward their N termini; however, NF κ B proteins can be subdivided into two distinct groups based on sequences C-terminal to the RHD. One group (including p50/p105, p52/p100, and Relish) contains C-terminal sequences that fold back to inhibit the RHD, and thus these C-terminal sequences must be removed to release the active DNA-binding protein (i.e., p50 or p52 from the precursors p105 and p100, respectively). A second group (c-Rel, RelA, RelB, Dorsal, and Dif) contains C-terminal sequences that are not cleaved and are required for these proteins to activate transcription.

NF κ B proteins bind to 9–10 bp DNA sites, called ' κ B sites', located in the regulatory regions of many cellular and viral promoters. To bind DNA, NF κ B proteins must form dimers. These dimers can, with few exceptions, contain any combination of homodimer or heterodimer, although the most common NF κ B dimer in many cell types is a p50–RelA dimer (Figure 1(b)). The affinity of the various NF κ B subunits for one another and the affinity of the various dimers for specific target DNA sites can vary greatly. These two considerations provide an array of diversity in the NF κ B dimers that are found in different cells, on the DNA sites that can be recognized by different NF κ B dimers, and in the genes (and consequently cellular responses) that these dimers regulate.

Regulation of NF κ B Activity

In most cells, NF κ B is present in the cytoplasm in an inactive state, due to interaction with a family of inhibitor proteins,

Figure 1 NFκB proteins. (a) Shown are the generalized structures, protein names, and genes encoding the two classes of NFκB proteins and the IκB proteins. RHD, Rel Homology domain; N, nuclear localization signal; vertical bars, ankyrin repeats. (b) X-ray crystal structure of the NFκB p50–RelA (p65) dimer on DNA. Table 1 Some inducers of NFκB activity

General category	Examples
Bacteria	<i>Salmonella</i> , <i>Staphylococcus</i> , Lipopolysaccharide
Viruses	HTLV-1, Epstein–Barr virus, hepatitis B virus
Cytokines	Interleukins, tumor necrosis factor
Oxidative stress	Hydrogen peroxide, reperfusion ischemia
Growth factors/ hormones	Platelet-derived growth factor, epidermal growth factor, insulin, transforming growth factor
Drugs	Various chemotherapeutic agents

termed ‘inhibitor of κB (IκB)’ proteins. IκB proteins include IκBα, IκBβ, IκBε, IκBζ, Bcl-3, and the C-terminal sequences of the NFκB precursor proteins p105 and p100. All IκB proteins contain multiple ~30 amino acid repeats called ankyrin repeats, which are protein–protein interaction domains. Through these ankyrin repeats, a single IκB protein binds directly to protein sequences in the RHD of an NFκB dimer. Binding of an IκB to NFκB inhibits the activity of the dimer in two ways: it causes NFκB to be in the cytoplasm and it blocks NFκB DNA binding. In some cases, especially with IκBζ and Bcl-3, the NFκB–IκB complex can still bind to DNA and the IκB protein serves as a transcriptional co-activator.

A variety of inducers (Table 1), including many cytokines, cell stresses, and viral or bacterial infections, can activate NFκB. Often the pathway is initiated by binding of an extracellular ligand to a cell-surface receptor; for example, tumor necrosis factor binding to its receptor or a bacterial or viral antigen to a Toll-like receptor. Engagement of the receptor by ligand causes receptor clustering, which promotes the recruitment of adaptor molecules to the intracellular domain of the receptor complex. In almost all cases, NFκB activity is then induced through activation of a cytoplasmic kinase complex called ‘IκB kinase (IKK)’. IKK is composed of three subunits: two related kinases (IKKα and IKKβ) and a scaffold protein called NEMO. Activation of the IKK complex generally requires phosphorylation of residues in the activation loop of the IKKβ kinase, and probably also posttranslational modifications of NEMO. Activated IKK then phosphorylates the IκB protein, which, in turn, acts as a signal for IκB to be degraded by the ubiquitin–proteasome

pathway. The liberated NFκB dimer can then enter the nucleus and bind to specific sites on DNA to activate target gene expression. Activation of NFκB is usually transient (often lasting no more than 30 min) primarily because one of the NFκB target genes is the gene encoding IκB. Therefore, newly synthesized IκB can cause NFκB to be resequenced in an inactive form in the cytoplasm, thus returning the pathway to its original inactive state.

Although the overall pathway of activation is similar (as in Figure 2), there are actually two distinct pathways for activation of NFκB, depending on the nature of the IκB protein and IKK subunit involved. In one pathway (the classical or canonical pathway), a separate IκB molecule, such as IκBα bound to p50–RelA, is phosphorylated by the IKKβ subunit, which leads to the complete proteolysis of IκBα. In a second NFκB activation pathway (called the alternative or noncanonical pathway), which involves a complex such as p100–RelB, a C-terminal site in p100 is phosphorylated by IKKα, which then leads to the partial proteolysis of the C-terminal ankyrin repeat sequences of p100, ultimately yielding an active p52–RelB dimer, which can also translocate to the nucleus to regulate gene expression.

The activity of NFκB is further modulated by mechanisms in addition to interaction with IκB proteins. For example, NFκB proteins can undergo posttranslational modifications (such as phosphorylation, acetylation, and methylation) that affect their activity, they can interact with a variety of other proteins (including many other transcription factors), and the IKK proteins can also have effects on chromatin-binding proteins to affect gene expression from κB site-containing promoters.

Genes and Biological Processes Regulated by NFκB

Normal Biological Roles for NFκB

There are over 300 genes whose transcription is known to be directly regulated by NFκB activity, and these genes are involved in a multitude of biological processes (Table 2). However, a variety of genetic and cellular studies have established that one of the key and evolutionarily conserved functions of NFκB is in regulating the innate immune response.

Figure 2 The NFκB signal transduction pathway. Under most circumstances, NFκB dimers (e.g., p50–RelA) are located in the cytoplasm of cells bound to inhibitory IκB proteins. Upon receiving an inducing signal, an IκB kinase (IKK) is activated. Active IKK phosphorylates IκB, and phosphorylated IκB then serves as a substrate for the ubiquitin–proteasome degradation pathway. Free NFκB can then enter the nucleus to increase or decrease specific target gene transcription. The system is eventually returned to its resting state through an auto-regulatory system, in that NFκB turns on expression of the gene encoding IκB, and newly synthesized IκB then re-sequesters NFκB in the cytoplasm.

Table 2 Some biological processes and relevant genes regulated by NFκB

Biological process	Relevant NFκB target genes
Angiogenesis	Vascular endothelial growth factor (VEGF)
Apoptosis	Bcl-X1, Bcl-2, IAP, TRAF, Fas
Cell adhesion	ICAM-1, VCAM-1
Cell growth	Cyclin D1, c-Myc
Stress	Cyclooxygenase, superoxide dismutase, nitric oxide synthetase
Innate immunity	Interleukins, interferon, tumor necrosis factor
Viral promoters	HIV-1, cytomegalovirus

In *Drosophila*, the Dorsal, Dif, and Relish proteins are induced to enter the nucleus by bacterial and fungal pathogens. These fly NFκB proteins then directly increase the expression of a family of genes called ‘cecropins’, which encode antifungal and antibacterial peptides. In mammals, many genes that encode antibacterial peptides, cytokines, and interferons are rapidly induced after infection with various viral and bacterial pathogens. Moreover, mice in which individual genes for c-Rel, RelB, p50, and p52 are disrupted (knockout mice) have defects in T- and B-cell-mediated immune responses. For example, c-rel knockout mice have B cells with greatly reduced survival and proliferation in response to antigen stimulation.

NFκB proteins are, however, also involved in the control of several other genes and processes that are not directly related to

Table 3 Some diseases associated with chronic NFκB activation

Arthritis
Asthma
Cancer
Diabetes
Inflammatory bowel disease
Ischemia/reperfusion damage
Sepsis

immunity. These include certain developmental processes, apoptosis, cell growth, and cell stress. In terms of development, NFκB activity (as directed by Dorsal) is required for the proper establishment of dorsal–ventral polarity in the early *Drosophila* embryo. In mammals, NFκB activity is involved in proper limb development, due to the regulation of a gene called *Twist*.

NFκB transcription factors also regulate cell survival in many contexts, either by promoting or, more often, by inhibiting apoptosis. For example, NEMO, IKKβ, and RelA are each required to protect embryonic liver cells from apoptosis induced by tumor necrosis factor, and knockout mice missing each of these factors die embryonically due to severe liver degeneration. Thus, the genes encoding several inhibitors of apoptosis are activated by NFκB.

NFκB and Disease

Aberrant NFκB activity has been implicated in several human diseases (Table 3), including many cancers and chronic inflammatory diseases, such as inflammatory bowel disease, asthma, and arthritis.

Many cancer cells have constitutively active, nuclear NFκB activity. In certain B-cell malignancies, notably diffuse large B-cell lymphoma, Hodgkin’s lymphoma, and multiple myeloma, NFκB activity is dysregulated due to either amplification of the c-rel gene, mutations that inactivate the gene encoding IκB, or mutations in genes encoding upstream activators of NFκB signaling. Furthermore, several oncogenic human viruses, such as Epstein–Barr virus (B-cell lymphoma and nasopharyngeal carcinoma), HTLV-1 (T-cell leukemia), and hepatitis B virus (liver cancer), encode proteins that activate NFκB. However, in many other cancers one finds chronic nuclear NFκB activity, which is usually made up of p50–RelA dimers, in the apparent absence of mutations in the NFκB signaling pathway or associated viral infection. That increased NFκB activity is important for the growth and survival of several cancers is verified by studies showing that inhibition of NFκB activity often causes the tumor cells either to die (undergo apoptosis) or to become more sensitive to apoptosis-inducing agents.

Because NFκB controls the expression of many cytokines, it is also consistently active in many situations involving acute or chronic inflammation. Moreover, in several animal model systems inhibition of NFκB activity can reduce inflammation. For example, mice with knockouts in the genes encoding p50 or c-Rel are resistant to experimentally induced arthritis. Finally, several human immunodeficiency diseases are caused by mutations that reduce activation of NFκB in response to pathogen infection; for example, mutations in the gene

Table 4 Some inhibitors of NFκB signaling

<i>Inhibitor</i>	<i>Molecular target</i>
Aspirin (high doses)	IKK
Curcumin	IKK
Glucocorticoids	RelA
Green tea compounds	IKK
Bortezimib	Proteasome
Sulindac	IKK

encoding NEMO are often the cause of the human immunodeficiency disease incontinentia pigmentosum.

Pharmacological Regulation of NFκB Activity

Because of the role of increased NFκB activity in inflammatory diseases and cancer, NFκB has received much attention as a molecular target for pharmacological intervention. As a multi-component pathway, NFκB activation can be inhibited at a variety of levels, including activation of IKK, IKK-mediated phosphorylation of IκB, ubiquitination and proteasome-mediated degradation of IκB, nuclear translocation of NFκB, and DNA binding and transactivation by NFκB. Indeed, NFκB inhibitors that act at each of these steps have been described (partial list in Table 4). Nevertheless, to date, most research effort has focused on identifying NFκB inhibitors that target the IKK complex, due to its central role in controlling the NFκB pathway and to successes in identifying specific kinase inhibitors in other systems.

Several natural products with anticancer or anti-inflammatory activities have been shown to inhibit activation of NFκB. These natural NFκB inhibitors include gold compounds (anti-arthritis), green tea (anticancer), curcumin (anticancer and anti-inflammation), and various plant extracts (anti-inflammation). In addition, some commonly used anti-inflammatory compounds, such as glucocorticoids, ibuprofen, and aspirin, have been reported to have anti-NFκB activity in

experimental model systems; however, in these cases, it is not clear that their biological effects in people are exerted through inhibition of NFκB.

Because NFκB is constitutively active in many cancers, clinical trials are underway with several compounds known to inhibit NFκB. These trials have reported promising results in the use of bortezimib, a small-molecule inhibitor of the proteasome, for the treatment of multiple myeloma, an NFκB-dependent B-cell cancer. Such compounds inhibit activation of NFκB by blocking proteasome-mediated degradation of IκB.

Glossary

ATP synthetase/hydrolase An enzyme of the inner membrane able to form adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate by utilizing the energy of the proton gradient generated during the oxidation reactions catalyzed by the respiratory chain complexes. It can also form a proton gradient by hydrolyzing ATP to ADP and inorganic phosphate.

Chaperones Proteins that promote the folding or unfolding of proteins; in the present context, they also facilitate association of subunit polypeptides into hetero-oligomeric proteins.

Eukaryotes Organisms with cells having a nucleus enclosed by a membrane.

Organelle A structure or membrane-enclosed compartment of a cell.

pet mutants Viable mutants able to derive ATP from glycolysis but not from oxidative phosphorylation.

Proteome Denotes all of the proteins of an organism or compartment of the cell.

Respiration In the biochemical sense used here, it is the process by which the electrons and protons extracted from reduced fuels such as carbohydrates, fats, and proteins are transferred to oxygen.

rho zero mutants Mutants devoid of mitochondrial DNA.

TIM complex An organized assembly of proteins that mediates the translocation of proteins from the TOM complex to the inner membrane or matrix of mitochondria.

TOM complex An organized assembly of proteins that mediates the translocation of a protein from the cytoplasm to the intermembrane space of mitochondria.

Only a small fraction of the protein constituents of mitochondria is encoded in the small vestigial genome of the organelle. Most of the genes governing the biogenesis of mitochondria reside in the chromosomal DNA of the nucleus. Referred to as *PET* genes, they represent a sizable fraction of the total genetic information in the nucleus. *PET* genes code for the enzymes making up the different metabolic pathways housed in mitochondria, for the substrate and protein transport systems, for the transcriptional, translational machineries involved in expression and regulation of mitochondrial genes, and for proteins governing fusion and fission of mitochondria.

Historical Background

All life depends on adenosine triphosphate (ATP), the universal currency of biological energy. The chemical energy inherent in the structure of this molecule is used to support a large number of different of phenomena including chemical, osmotic, electrical, and mechanical work. Most of the ATP in eukaryotic organisms is supplied by the mitochondrion, a complex cellular organelle composed of two membranes (outer and inner) and two soluble compartments (intermembrane space and matrix). Biogenesis of mitochondria occurs by replenishment and addition of newly synthesized proteins and phospholipids to the pre-existing organelle. In dividing cells, there is a net increase of mitochondrial mass, which is distributed among the progeny. This process is aided by the ability of mitochondria to undergo fusion and fission. Mitochondria, therefore, are not synthesized *de novo* but rather serve as a template for their own faithful replication. The genetic determinants of mitochondria are

located in two physically separate compartments of the cell. Most of the information is provided by the *PET* genes of the nucleus, but a small number of genes present in mitochondrial DNA (mtDNA) are also indispensable for maintenance of fully functional mitochondria.

The discovery of an extra-nuclear genetic element (*rho*) in yeast by Boris Ephrussi and the later demonstration by Gottfried Schatz that this factor corresponds to a unique DNA present in mitochondria were the foundations for much of the subsequent work aimed at understanding the function of this genome. Despite the large variability in the organization, mode of expression, and gene compositions of mtDNA among different members of the plant and animal kingdoms, some general statements can be made, nonetheless. Close to 3000 different mitochondrial genomes have been sequenced as of this writing. In all instances, at least some components of the mitochondrial translational apparatus such as the genes for the endogenous ribosomal RNAs and transfer RNAs (tRNAs) are encoded in mtDNA. Another important attribute of this genetic system is that it codes for a small number of mitochondrial proteins that encode proteins crucial for the respiratory and ATP-generating capacities of the organelle. In most organisms, the protein-coding genes of mtDNA specify several subunits of cytochrome oxidase, cytochrome *b*, and one or more subunits of the proton-translocating ATP synthetase/hydrolase. The *rho* zero mutants lacking this set of genes produce mitochondria that are defective in respiration and oxidative phosphorylation because they lack the genes for catalytically important components of the respiratory chain, ATP synthetase, and the ribosomal RNA and tRNAs needed for translation of the endogenous messenger RNA *s* (mRNAs).

A much larger share of the information essential for maintaining the structural and functional integrity of mitochondria is contributed by *PET* genes, which are located in the chromosomal DNA of the nucleus.

Origin of Nuclear Gene Products with Functions in Mitochondria

The endosymbiont hypothesis, first proposed by Lynn Margulis in 1968, was a landmark advance in our thinking of how cells evolved in response to major changes in their environment. According to this hypothesis, many organelles of modern-day eukaryotic cells, including mitochondria and chloroplasts, are stripped-down products of what originally were free-living bacteria. In the case of mitochondria, a nucleated cell dependent on glycolysis as its sole source of ATP was invaded by a bacterium with an aerobic mode of energy metabolism. Such unions, when advantageous to the host, became fixed during evolution. There is compelling evidence to support the bacterial origin of subcellular structures that inhabit eukaryotic cells. Most notably is the presence in mitochondria and chloroplasts of autonomously replicating genomes, and of all the enzymatic machinery needed to express the encoded genes into their respective RNA and protein products. Significantly, the transcriptional and translational machineries of mitochondria and chloroplasts are much more related to their bacterial counterparts than to those operating in the cytoplasm of eukaryotic cells.

The extent to which the mitochondrial genome contributes toward the propagation of the organelle has been severely reduced due to a continual transfer of genetic information to the host's nuclear DNA. Today, the existence of mitochondria relies in large measure on the expression of gene products encoded in nuclear DNA. The loss of mitochondrial autonomy is clearly evident from the properties of cells that have been depleted of mtDNA. Such genome-less variants termed *rho* zero mutants have been created in yeast and mammalian (e.g., human) cells. Despite the complete absence of mitochondrial DNA, *rho* zero mutants contain subcellular structures with the characteristic morphology and most of the metabolic pathways of mitochondria. These observations point to the nonessentiality of mtDNA for the perpetuity of mitochondria, but do not minimize the importance of this genome for their functional competence.

Number of Mitochondrially Related Nuclear Genes

The number of distinct proteins in yeast mitochondria is still not known precisely but based on large-scale subcellular localization studies with the unicellular yeast *Saccharomyces cerevisiae*, 700–800 is a reasonable estimate. This corresponds to approximately 10–12% of the different proteins known to exist in this organism. Of course, this number will vary in more complex eukaryotes, where depending on their tissue of origin, mitochondria may have become highly specialized with a lesser functional complexity. For example, in mammals, mitochondria of organs such as heart and muscle have simpler metabolic profiles than those of liver and consequently have fewer proteins.

Yeast as a Model for Mitochondrial Studies

For practical reasons, *S. cerevisiae* has become an important model for the study of *PET* genes. A vast arsenal of genetic and biochemical tools is directly applicable to the analysis of mitochondria in this organism. Also available are the complete sequences of the 16 nuclear chromosomes and of mtDNA. Finally, because of its status as a facultative anaerobe, this yeast is able to tolerate most mutations that impair mitochondrial function as long as it is supplied with a fermentable source of carbon and energy.

Most of what we presently know about *PET* genes stems from three different sources. An important body of information has been derived from traditional studies of the intermediary metabolism carried out by mitochondria. In some instances, such studies have predated the discovery of mitochondria as the cellular repository of the pathways in question. Genetic analysis has played an equally important role. Respiratory defective mutants of yeast have been instrumental in defining many nuclear genes that impinge on all aspects of mitochondrial function, biogenesis, and human pathologies. More recently, the high-throughput proteomic approach has further augmented the list of mitochondrially related gene products, most with yet-to-be-understood functions.

Gene Functions

Based on the phenotype of the respective mutants, *PET* genes can be either essential or nonessential. Nonessential genes, which make up the larger class, are defined by *pet* mutants. Such strains are viable but because of their genetic lesions are unable to produce ATP by means of oxidative phosphorylation. The products of *PET* genes have functions that are related either directly or indirectly to mitochondrial metabolism, but not to the continuity of mitochondria as a structural compartment of the cell. The second, less abundant class consists of essential genes needed for the survival of the cell. Their products provide functions relevant to the structural integrity of mitochondria or to some essential aspect of metabolism. Mutations in the latter prevent growth on both fermentable and nonfermentable substrates.

Nonessential *PET* Genes

These genes encompass a wide range of mitochondrial functions. The most important, from a quantitative point of view, are involved in the expression of the products encoded in mtDNA (Figure 1). They consist of proteins that function in replication of mtDNA, and transcription and processing of mitochondrial RNA. In yeast, they also code for all except one of the mitochondrial ribosomal proteins, as well as most of the tRNA synthetases and translation initiation, elongation, and termination factors. A second important group of genes code for proteins that catalyze most of mitochondrial metabolism. This includes enzymes of the tricarboxylic acid (TCA) cycle, fatty acid metabolism, some aspects of amino acid biosynthesis, and a number of other pathways needed for the synthesis of important cofactors such as hemes A and B, coenzyme Q, and lipoic acid.

Figure 1 Dependence of mitochondrial gene expression on products of *PET* genes. The dashed blue arrows show some of the functions contributed by nuclear DNA for expression of the mitochondrially encoded subunits of the ATPase and respiratory enzymes. In yeast the pre-mRNAs can be multigenic transcripts that are matured by excision of intronic sequences and endonucleolytic cleavages. Some proteins are synthesized as precursors (pre-protein) with amino-terminal sequences that are removed by specific proteases. The solid blue arrows denote *PET* gene products targeted to the outer membrane (OM), intermembrane space (IMS), inner membrane (IM), and internal matrix compartment. The broken arrows indicate nuclear factors that act at different stages of mitochondrial gene expression and promote insertion of the resultant products into the inner membrane.

Figure 2 Schematic representation of the respiratory complexes and ATP synthetase in the mitochondrial inner membrane. The four complexes of the respiratory chain are NADH-coenzyme Q reductase or complex I (yellow), succinate-coenzyme Q reductase or complex II (yellow), coenzyme QH₂-cytochrome c reductase or complex III (red), and cytochrome c oxidase or complex IV (green). Coenzyme Q is denoted by the small orange circles and cytochrome c by the pink circle. The ATP synthetase/hydrolase or complex V is shown with the F₁ ATPase protruding into the matrix compartment. In addition to catalyzing the transfer of electron from NADH and FADH₂ to oxygen, three of the complexes promote the vectorial transfer of protons from the matrix to the intermembrane space (IMS). Protons are recycled by the ATP synthetase during synthesis of ATP from ADP and inorganic phosphate.

The ATP synthetase/hydrolase and the enzymes making up the respiratory chain (Figure 2) are all hetero-oligomeric proteins, with more than a dozen different subunit polypeptides in most cases. Assembly of the subunits into the final holoenzymes is a complex process that requires the assistance of nuclearly encoded factors. Some of the chaperones act by facilitating a topologically correct insertion of specific subunits into the inner membrane, by preventing nonproductive

interactions of hydrophobic proteins, or by still other unknown mechanisms. Because these chaperones target specific subunits, they represent a substantial fraction of the total number of mitochondrial proteins. For example, some dozen nuclear mutants have been reported to be cytochrome oxidase deficient due to mutations in proteins that affect late events in assembly of this single enzyme. Recent evidence from studies of yeast has uncovered another group of important proteins

that regulate translation of mitochondrial gene products so that they are balanced with their functional partners expressed by the nucleo-cytoplasmic genetic system. Finally, many *PET* genes, coding for novel proteins, still lack functions that can be assigned at this time.

Essential *PET* Genes

The highly regulated metabolism of eukaryotic cells depends on the sequestration of the enzymes making up the various pathways in their appropriate compartments. Proteins translated in the cytoplasm but destined to function in one of the internal compartments of mitochondria are imported and sorted by means of the TOM and TIM translocases of the outer and inner membranes, respectively. Mutations in components of either of these protein transport systems are lethal to the cell for several reasons. An immediate effect of the transport defect is a mis-localization of proteins in the cytoplasm. This abrogates the accretion of newly synthesized material by mitochondria, resulting in their eventual loss.

Mitochondria house proteins that function in pathways essential for the overall economy of the cell. For example, certain steps of heme B biosynthesis occur in mitochondria. Since heme B is a prosthetic group of enzymes (e.g., P450 hydroxylases) other than those involved in respiration, cells unable to produce heme B are not viable. This also applies to certain enzymes of amino acid biosynthesis located in mitochondria. In animals, carbamoyl synthetase and ornithine transcarbamylase, two important enzymes of arginine biosynthesis, catalyze their respective reactions in the mitochondrial matrix. Mitochondria also house the pathway for producing the iron-sulfur prosthetic groups of a large number of redox proteins that function not only in mitochondria but also in the cytosol.

Some nuclear genes code for proteins that are apportioned between the cytoplasm and mitochondria. This is true for some tRNA modification enzymes and for aminoacyl-tRNA synthetases. In yeast, six mitochondrial aminoacyl-tRNA synthetases are expressed from nuclear genes that also code for the same cytoplasmic enzymes. Mutations in these essential genes, therefore, result in cell lethality.

Regulation

Many *PET* genes of yeast are regulated at the level of transcription by oxygen and carbon source. Oxygen stimulates the synthesis of heme in mitochondria mainly at later steps of the pathway catalyzed by oxygenases. Heme activates the binding of the Hap1 transcriptional activator to the upstream activation sites of some genes for respiratory chain proteins such as cytochrome *c*, thereby activating their transcription. Glucose has the opposite effect. It suppresses transcription of genes involved in alternative fuel usage by means of a complex regulatory pathway called catabolite repression. In the absence of glucose, repression is relieved and transcription of glucose-responsive

genes is enhanced by the Hap2/3/4/5 transcriptional activator complex.

Mitochondrial gene expression is regulated primarily at the posttranscriptional level by products of *PET* genes. Mitochondrial RNA polymerase recognizes a simple promoter and there is little regulation of its activity except that it is more abundant in the absence of glucose and the presence of oxygen. Most mitochondrial genes are transcribed as long multi-genic RNAs. Points of regulation include processing of 5' and 3' ends of RNA to the mature length, excision of introns, and RNA stability. Initiation of translation is regulated by factors that attract ribosomes to the correct internal translational start sites of mitochondrial mRNAs. Posttranslation modification and assembly of the constituent subunits of the respiratory and ATP synthetase complexes also depend on the intervention of factors encoded by *PET* genes subject to these regulatory systems.

Human Disorders

A growing list of human pathologies has been related to mitochondrial defects and the responsible mutations mapped to RNA and protein-coding genes of mtDNA. Such mutations manifest a wide range of clinical phenotypes including encephalomyopathies, cardiomyopathy, deafness, diabetes, optic neuropathy, and dystonia. Similar presentations are elicited by mutations in nuclear DNA that affect mitochondrial metabolism either directly through lesions in the structural genes for enzymes of the TCA cycle, fatty acid oxidation, and mtDNA integrity or indirectly by interfering with metabolite and protein import, assembly of respiratory chain complexes, metal homeostasis, and protein turnover. In view of their central role in oxidative metabolism, a process dependent on a large number of nuclear *PET* genes, future studies of model organisms such as yeast can be expected to substantially increase the number of mitochondrially related diseases.

Glossary

CaaX A four-amino-acid peptide motif that directs the C-terminal isoprenylation of a protein. It is named for its consensus sequence: C, cysteine; a, an aliphatic amino acid; and X, any amino acid.

Chromatin Complex of DNA, histones, and nonhistone proteins contained within the nucleus of eukaryotic cells. Heterochromatin is transcriptionally inactive.

Electron microscopy A type of microscopy that resolves fine structural details of cells by using a focused beam of electrons to penetrate the specimen.

Integral membrane protein Membrane-bound protein containing one or more regions that span the hydrophobic core of the phospholipid bilayer.

Lamina Fibrous network of lamins and associated proteins on the inner surface of the nuclear envelope. Lamins are not related to extracellular laminin proteins.

Nuclear envelope Double membrane structure that surrounds the nucleus.

Nuclear pore complex Specialized channels that span the nuclear envelope, which are responsible for bidirectional transport of macromolecules between the nucleus and the cytoplasm.

Structure of the Nuclear Envelope

The first descriptions of the nuclear envelope were provided by nineteenth-century biologists, notably Fleming, who used light microscopy to examine the nuclei of plants and protozoa. A century later, the application of electron microscopy to the analysis of a variety of intracellular organelles revealed the unique structure and organization of the nuclear envelope. The nuclear envelope consists of two membranes, an inner membrane and an outer membrane, each of which is a bilayer of lipids and proteins (Figure 1). The intermembrane space, or lumen, is a site of calcium storage in the cell, and special channels in the membrane facilitate calcium release and re-uptake upon physiological stimulation. The outer nuclear membrane is continuous with the endoplasmic reticulum membrane, thus there is continuity between the lumen of the nuclear envelope and the lumen of the endoplasmic reticulum.

Structure of the Nuclear Lamina

In 1966, Fawcett published a seminal electron microscopy study showing the presence of a “fibrous lamina on the inner aspect of the nuclear envelope” in several cell types. The organization of the lamina as a meshwork of 10-nm-diameter filaments adjacent to the inner nuclear membrane was later revealed in samples prepared from frog oocyte nuclei (Figure 1).

Composition of the Lamina

The development of biochemical procedures for isolating nuclei from cells and for preparing the lamina–nuclear pore complex fraction from nuclei set the stage for identifying proteins that comprise the lamina.

Lamins

The major proteins of the nuclear lamina, termed lamins, are members of the intermediate filament protein superfamily. The molecular weights of lamins range from 60 to 70 kDa depending on the isoform, and all lamins have related primary and secondary structures. The amino- and carboxyl-terminal domains of lamins are globular, the latter encoding a nuclear localization signal. Like other members of the intermediate filament superfamily, lamin proteins contain a central rod domain composed of four α -helical segments that mediate coiled-coil interactions resulting in the formation of lamin dimers (Figure 2). Lamin dimers assemble into tetramers, which, in turn, assemble into 10-nm-diameter filaments that comprise the nuclear lamina. The approximately orthogonal arrangement of lamin filaments observed by electron microscopy implies the presence of proteins that mediate interfilament cross-links; however, the proteins and interactions that establish and maintain this higher-order structure have not yet been identified.

Lamin Genes

Lamins are classified as A type and B type. The B-type lamins are expressed in most cell types, whereas A-type lamins, which include lamin C, are generally expressed in differentiated tissues. In some tissues, lamin A/C is not expressed until after birth. There is a single lamin A gene (*LMNA*) in mammals that, through alternative splicing, produces transcripts for two lamin A isoforms and one lamin C isoform. There are two lamin B genes (*LMNB1* and *LMNB2*) that together encode three lamin B isoforms. The phylogenetic distribution of lamins extends to invertebrates, but lamins are absent from plants and fungi.

Figure 1 The nuclear membrane viewed by light and electron microscopy. (a) Differential interference contrast microscopy of a cell showing the nuclear envelope. Scale = 5 μm . (b) Thin section electron microscopy showing a small region of the nuclear envelope and associated structures. Scale = 0.2 μm . (c) Metal-shadowed nuclear lamina from a frog oocyte viewed by electron microscopy. Scale = 0.5 μm . (c) Modified from Aebersold U, Cohn J, Buhle L, and Gerace L (1986) The nuclear lamina is a meshwork of intermediate-type filaments. *Nature* 323: 560–564.

Figure 2 Structure of the nuclear lamina is regulated by phosphorylation. Lamin filaments undergo phosphorylation by kinases in mitosis, causing disassembly into lamin dimers. At the end of mitosis, the lamins are dephosphorylated by phosphatases, which return the lamins to an assembly competent state.

Lamin-Associated Proteins

A group of integral membrane proteins, which are unique to the inner nuclear membrane, bind directly to nuclear lamins and play critical roles in modulating lamina structure and function. This group includes LAP2, Emerin, Man1, and LBR. These proteins are anchored in the inner nuclear membrane by hydrophobic, membrane-spanning segments, while the rest of the protein projects into the nucleoplasm, where it contacts the lamina. Lamin-associated proteins also interact with DNA-binding proteins such as BAF and GCL that mediate chromatin-attachment to the nuclear membrane. In addition, lamin-associated proteins are part of a network of polypeptides that link the nucleoplasm to the actin filaments in the cytoplasm.

Functions of the Lamina

The nuclear lamina performs both structural and regulatory functions. These functions are not mutually exclusive, because alterations in structure can change the capacity of the nuclear lamina to regulate nuclear functions. Characterization of the regulatory functions of the nuclear lamina is a relatively recent area of investigation, and this knowledge base should expand dramatically in the next several years.

Nuclear Envelope Assembly after Mitosis

Disassembly of the nuclear envelope and lamina occurs at prometaphase, a period of the mitotic cell cycle that precedes

chromosome segregation. The nuclear envelope fragments into membrane vesicles and the lamin filaments are disassembled into lamin dimers. Near the end of mitosis in late anaphase, the nuclear envelope-derived vesicles and lamin proteins are reassembled around the chromosomes of the two new daughter cells. The reassembly pathway involves multiple steps, beginning with the binding of lamins and vesicles to the surface of chromosomes. The vesicles then fuse to generate membranes. The incorporation of lamins into the lamina continues after membrane formation by virtue of nuclear import of lamins through newly formed nuclear pore complexes.

Nuclear Size

Experimental manipulation of the nuclear reassembly pathway has shown that lamins and lamina-associated proteins are necessary for the several-fold increase in volume of the nucleus during the cell cycle. The lamina is, therefore, a critical regulator of nuclear size.

Nuclear Shape and Rigidity

The lamina forms a cage-like structure within the nucleus and is tethered to the inner nuclear membrane. As such, the lamina plays a major role in defining nuclear shape. A striking example of how lamins determine the shape of the nucleus is lamin B3, a lamin isoform that was shown by Furukawa and Hotta in 1993 to be responsible for the unusual hook shape of nuclei in spermatocytes. The lamina also provides rigidity that resists deformation and aids in restoration of shape following deformation. Nuclei from the nematode *Caenorhabditis elegans*, rendered lamin deficient, show little resistance to deformation, and a failure to restore nuclear shape.

Positioning of Nuclear Pore Complexes

Nuclear pore complexes span both the inner and outer nuclear membranes. Integration of nuclear pore complexes into the membrane is mediated by GP210, an integral membrane protein. The relative spacing of nuclear pore complexes in the two-dimensional plane of the nuclear envelope is maintained by the nuclear lamina. B-type lamins mediate this spacing through direct interactions with nuclear pore complexes. Loss of this functionality results in a failure to maintain the proper distribution of nuclear pore complexes in the nuclear envelope.

Regulation of Gene Expression

Lamins can have a positive or negative influence on gene expression, depending on the context. Lamins and lamina-associated proteins bind to chromatin, resulting in the attachment of a subset of chromatin to the inner nuclear membrane which can be observed by microscopy. Because there is a strong correlation between localization of chromatin at the nuclear periphery and gene silencing, the nuclear lamina has historically been viewed as a scaffold for anchoring transcriptionally inactive heterochromatin. Lamin B is highly concentrated at the

inner nuclear membrane, and, together with several DNA-binding proteins that repress transcription, mediates the negative influence on transcription at the nuclear periphery. By contrast, it has been shown that lamin A can turn on expression of muscle-specific genes, a clear indication of positive effects on transcription. Lamin A is found at both the inner nuclear membrane and throughout the nucleoplasm, and the latter pool is thought to promote transcription. Thus, whether lamins influence transcription positively or negatively is dependent on the particular lamin protein, and its subnuclear distribution.

Regulation of DNA Replication

Lamins play an important role in DNA replication by facilitating the recruitment of proteins needed for initiation of replication. The original link between lamins and DNA replication was made by Newport and colleagues in 1990, using a system that reconstitutes nuclear assembly *in vitro*. Depletion of lamin B from the system resulted in small nuclei that failed to initiate DNA synthesis. Subsequent experiments have implicated lamina-associated proteins in DNA replication as well.

Posttranslational Modification of the Lamina

The lamin proteins are subject to modifications that profoundly affect function.

Phosphorylation

Gerace and Blobel showed in 1980 that phosphorylation is used as a molecular switch to control the assembly properties of lamins. Disassembly of lamin filaments at prometaphase is driven by lamin phosphorylation (Figure 2). Lamin disassembly occurs specifically at prometaphase because the kinase that mediates lamin phosphorylation is activated during the mitotic phase of the cell cycle. The phosphorylated lamins are subsequently dephosphorylated by phosphatases, rendering them competent for reassembly into filaments in late anaphase and telophase.

Isoprenylation

A cysteine-containing motif in the carboxyl terminus of lamin B, called a CaaX box, is the site for attachment of an isoprenyl group. This lipid moiety inserts into the inner nuclear membrane and mediates the stable membrane attachment of lamin B. During mitosis, lamin B remains stably associated with nuclear-envelope-derived vesicles. The isoprenylated carboxyl terminus of lamin A is removed by proteolysis. Lamin C is not isoprenylated because the CaaX box is not encoded in the lamin C transcript.

Proteolysis

Lamins are regulated by proteolysis in two functionally distinct pathways. After translation, the carboxyl-terminal 18 amino acids of lamin A are removed by the lamin-A-specific protease

Figure 3 Images of children that carry an HGPS mutation in lamin A. The pictures were taken when the children were 4 and 20 years of age (left and right panels, respectively), and are courtesy of the Progeria Research Foundation.

Zmpste24. This cleavage reaction removes the isoprenylated carboxyl-terminus and the capacity of lamin A to associate directly with membranes. During apoptosis, a group of proteases called caspases cleave the lamins at multiple sites. Lamin cleavage by caspases is commonly used as a biochemical indicator of apoptosis.

Lamins in Human Disease

Mutations in genes encoding proteins of the nuclear lamina cause human diseases, collectively called laminopathies. More than 300 mutations have been identified in *LMNA*, the gene encoding the lamin A/C proteins. Remarkably, different *LMNA* mutations give rise to at least a dozen different diseases, many with distinct phenotypes. The clinical severity of a particular *LMNA* mutation frequently varies, even among members of a given family. This indicates that penetrance of the phenotype can be highly dependent on the genetic background.

Emery–Dreifuss Muscular Dystrophy

Particular mutations in the genes encoding either lamin A or emerin proteins can cause Emery–Dreifuss muscular dystrophy. Patients display tendon contractures, degeneration of skeletal muscle, and electrical conduction problems in cardiac muscle. *LMNA* mutations are also linked to familial partial lipodystrophy, which causes partial loss of fat tissue and late-onset insulin-resistant diabetes. A major unanswered question is how laminopathies are manifest in specific tissues because lamins are expressed in all cell types. Currently, there are two hypotheses addressing the tissue-specific basis of laminopathies, particularly those affecting muscle function. The structural hypothesis proposes that muscular dystrophies result from fragile nuclei that are susceptible to muscle contraction-induced physical damage. The gene-expression hypothesis is based on the concept that lamin deficiencies alter nuclear architecture in a manner that changes the pattern of gene expression. Tissues affected by laminopathies are derived

from the mesoderm, suggesting lamin A plays a particularly critical role in development of this cell lineage.

Hutchinson–Gilford Progeria Syndrome

In 2003, research groups in the United States and France discovered that mutations in *LMNA* are responsible for the premature aging disease progeria. A rare disease with an incidence of 1 in 4 million births, phenotypes associated with progeria are manifest after birth, and include reduced subcutaneous fat, alopecia, and complications of the cardiovascular system (Figure 3). Children with progeria die of heart attack and stroke at an average age of 13.

Progeria mutations in the *LMNA* gene generate a form of the lamin A protein (termed Progerin) that is defective for posttranslational modification. Progerin lacks the proteolytic cleavage site that normally releases lamin A from its membrane anchorage mediated by an isoprenyl group. Constitutive attachment of Progerin to the membrane of the inner nuclear envelope is the source of dominant effects on nuclear morphology and function. The mechanism by which Progerin effects are transduced throughout the cell are still under investigation.

Glossary

Chromosome territories Specific regions within the nucleus that are occupied by a given chromosome.

Epigenetics Heritable changes in gene expression that are not due to alterations in DNA sequence.

Euchromatin Gene-rich regions of the genome that decondense during interphase of the cell cycle to allow for transcription.

Heterochromatin Gene-poor regions of the genome that possess repetitive elements and remain condensed throughout the cell cycle.

Histones Small basic proteins that assemble into nucleosomes, the fundamental packaging unit of chromatin.

Lamina The network of proteins, including lamins, that lines the inner side of the nuclear envelope.

Nuclear envelope A layer of two membranes that encapsulates the nucleus and is punctuated with pores.

Nuclear Envelope

A distinguishing feature of the eukaryotic cell is the presence of a nucleus. The nucleus is partitioned from the cytoplasm by the nuclear envelope, which is composed of an inner and outer membrane (Figure 1). The nuclear envelope is studded with nuclear pores that allow for shuttling of macromolecules between the nucleus and cytoplasm. The inner side of the nuclear envelope is lined with a network of intermediate filament proteins called lamins, which interact with additional proteins that possess an LEM domain (a conserved stretch of amino acids first identified in the proteins LAP2, emerin, and MAN1) (Figure 1). Collectively, these proteins make up the nuclear lamina, which provides structural support for the nucleus, plays a role in DNA replication, and participates in signal transduction. LEM domain proteins also interact with the small DNA-binding protein barrier-to-autointegration factor (BAF) that connects the lamina with chromatin, providing anchor points for organization. The lamina contains SUN domain proteins (possessing a conserved amino acid sequence first identified in Sad1p and UNC-84) that span the inner nuclear membrane and connect with KASH domain proteins (possessing a conserved amino acid sequence first identified in the proteins Klarsicht, ANC-1, and Syne Homology) within the peri-nuclear space (Figure 1). KASH domain proteins interact with cytoskeletal components such as actin (Figure 1). Thus, a series of protein–protein interactions link the cytoplasm and nucleus, which allows for signals to be transmitted between the cellular compartments.

Chromatin Packaging

A function of the nucleus is to house the genomic DNA. The DNA is wrapped around histones and associated with nonhistone chromosomal proteins that collectively make up chromatin. The smallest unit of chromatin is the nucleosome, which is composed of 146 base pairs (bp) of DNA wrapped twice around an octamer of the core histone proteins H2A, H2B, H3, and H4. In most eukaryotes, a variable region of linker

DNA associates with linker histone H1 between histone octamers. Interactions among nucleosomes are thought to facilitate chromatin folding, which is responsible for condensing the DNA to ratios of 1:10 000. Chromatin condensation allows chromosomes that are centimeters in length to fit into a nucleus that is 6 μm (1/1500th of a centimeter) in diameter, a major packaging feat.

Depending on the cell type, different regions of the genome are loosely packaged into transcriptionally competent euchromatin, allowing for gene expression. Other regions are highly packaged into transcriptionally silent heterochromatin. In nearly all cells, repetitive DNA sequences located near the centromeres of chromosomes are packaged into constitutive heterochromatin that remains condensed throughout the cell cycle. In contrast, facultative heterochromatin contains genes that are silenced but can be reactivated by repackaging into euchromatin at specific times in development or upon environmental stimulation. The inactive X-chromosome in mammalian females, also known as the Barr body, is an example of facultative heterochromatin. In somatic cells, one of the two X-chromosomes of the female is inactivated upon differentiation. This inactivation equalizes the amount of gene product produced from the X-chromosome in males and females.

Atop the hierarchy of chromatin packaging are epigenetic modifications of the DNA and histones that influence chromatin compaction and nuclear processes, including gene expression, DNA replication, and DNA repair. Epigenetic literally means ‘above the genes’ and refers to the addition of specific chemical groups to DNA, such as cytosine methylation, and posttranslational modifications to histones, such as acetylation of lysine residues on histone tails. These modifications mark genomic regions and can persist through cell divisions, but do not alter the underlying DNA sequence. DNA methylation can attract specific proteins that regulate gene silencing. Likewise, posttranslational modifications on histones can serve as docking sites for specific effector proteins that promote open or closed chromatin structures. Combinations of histone modifications are proposed to code for specific biological functions such as gene activation, gene repression, and chromatin condensation. Importantly, these epigenetic marks are reversible,

Figure 1 Diagram of the nuclear envelope. The nuclear envelope is composed of an outer nuclear membrane and an inner nuclear membrane that is lined with lamina. Nuclear pores punctuate the membrane and serve as conduits for the transfer of macromolecules between the nucleus and cytoplasm. LEM domain-containing proteins such as MAN1 and emerin associate with the inner nuclear membrane. The small DNA-binding protein BAF associates with LEM domains and connects the lamina to chromosomes. SUN domain proteins span the inner nuclear membrane and link to KASH domain proteins, which associate with cytoskeletal components such as actin. NPC, nuclear pore complex; ONM, outer nuclear membrane; INM, inner nuclear membrane.

Figure 2 Diagram of nuclear organization. Lightly shaded areas represent chromosome territories in which chromosomes (solid color lines) are confined. Darkly shaded overlays represent domains of heterochromatin, which are frequently at the nuclear periphery. Many types of nuclear bodies occupy interchromosomal spaces and are thought to represent storage sites for proteins and sites of specific nuclear processes.

which distinguishes them from permanent changes in the DNA sequence. This epigenetic plasticity allows the genome to respond to developmental cues and changes in the environment by altering gene expression.

Nuclear Organization and Gene Expression

Chromosomes are not randomly arranged within the nucleus, but exist within defined three-dimensional regions called chromosome territories (Figure 2). In the late 1800s and early 1900s, Carl Rabl and Theodor Boveri were among the first scientists to note the territorial organization of chromosomes. In the 1980s, the advent of chromosome painting technology provided the ability to visualize individual chromosomes by hybridization with fluorescent DNA sequences that recognize specific chromosomes. The results of such analyses supported a

territorial organization of chromosomes. Interchromosomal space makes up the nuclear volume that is not occupied by chromosomes and can vary in amount depending on the cell type. The interchromosomal space contains various types of nuclear bodies, which act as localized storage houses for nuclear factors and nucleoprotein assembly factories that carry out processes such as RNA splicing. The spatial relationship among human chromosome territories was recently determined using a molecular technique involving ligation of DNA segments that are in close proximity to one another, coupled with new massive sequence technologies. The results of these experiments generated a genome-wide map of chromosomal interactions at the 1-Mb level. The data strongly supported the existence of chromosome territories and demonstrated that the entire genome is arranged as a 'fractal globule' rather than an 'equilibrium globule', which suggests that the chromosomes are arranged as interdigitated territories, not intertwined strands.

The radial position of a chromosome (position along the axis that runs from the center of the nucleus to the nuclear edge) within the nucleus of interphase animal cells correlates with gene activity. This correlation is best illustrated by comparative studies of human chromosomes 18 and 19. Chromosome 19 is gene rich and resides within the nuclear interior, whereas gene-poor chromosome 18 is associated with the nuclear periphery. In support of the nuclear periphery as a silent zone, the majority of heterochromatin within many types of cells resides in close proximity with the nuclear envelope. This finding suggested the possibility that nuclear envelope-associated proteins might play a role in chromatin packaging and chromosome organization. Consistent with this idea, mutations in mammalian genes encoding lamins result in reduced levels of constitutive and facultative heterochromatin as well as altered gene expression.

To directly study the role of the nuclear periphery in gene expression, several research groups have designed experiments using a variety of model systems to tether a chromosomal region to the nuclear envelope. Tethering is accomplished by utilizing two molecular components. The first component is a cell line or transgenic organism that carries reiterated binding sites for the *Escherichia coli* LacI repressor protein (*lac* operator repeats) positioned upstream of a reporter gene. The second component is a transgene that expresses a fusion protein consisting of a DNA-binding domain of the LacI repressor and a nuclear envelope protein. Upon expression, the fusion protein binds upstream of the reporter gene. This association results in tethering of the chromosomal region possessing the reporter gene to the nuclear periphery via the LacI nuclear envelope fusion protein (Figure 3).

Using the fruit fly *Drosophila* as a model, association of a reporter gene with a lamin protein resulted in localization of the reporter to the nuclear envelope and silencing (Figure 3). As a negative control, association of a LacI-GFP (GFP, green fluorescent protein) with the reporter did not result in peripheral positioning or cause gene silencing. Association with LacI-lamin caused limited silencing, as expression of neighboring genes was unaffected. Results similar to these have been observed in mammalian cells where tethering with nuclear envelope proteins such as emerin, Lap2 β , and lamin showed differential effects on expression of neighboring genes on the chromosome. The lack of silencing in some cases might be due

Figure 3 Molecular tethering experiments used to direct reporter genes to the nuclear periphery. (a) Diagram of reporter genes inserted within the genome. The reporter gene has *lac* operator repeats (blue line) positioned upstream of the promoter (bent arrow) of a reporter gene. The *lac* operator repeats can be bound by a LacI-GFP fusion protein (green, top) as a negative control or a LacI-lamin protein (gray, bottom) as the experimental situation. (b) Nuclear localization of the reporter gene. Salivary gland nuclei from *Drosophila* larvae expressing the fusion proteins were stained with anti-LacI antibodies and the location of the reporter gene is indicated by a focus of intense staining (arrow). Note that association with LacI-lamin resulted in the localization of the reporter gene to the nuclear periphery. (c) Diagram of the effect of tethering LacI-lamin. The reporter gene was transcriptionally silenced (red bent arrow). However, a closely linked gene (green bent arrow) retained the ability to be expressed, despite close proximity to the nuclear envelope.

to proximity to nuclear pores. In yeast, high levels of gene expression are observed when genes are located close to nuclear pores. Differences in gene expression upon localization to the nuclear periphery might also be due to the local epigenetic chromatin landscape. Treatment with the drug trichostatin A, which inhibits histone deacetylase proteins, results in the accumulation of acetyl groups on lysine residues of histone tails and increased expression of genes associated with the nuclear envelope. Taken together, these studies demonstrate that proximity to the nuclear periphery is not sufficient for gene silencing, but may promote a silent state if conditions are favorable.

The position of genes within the nucleus is dynamic. Activation by developmental signals and/or environmental stimulation sometimes correlates with the movement of genes to the exterior edge of chromosomal territories, the interchromosomal space, or migration to the nuclear interior. This movement depends on nuclear actin and/or myosin, suggesting that these nucleoskeletal components play a role in the chromatin repositioning that occurs during transcriptional activation or repression.

Nuclear Position and Disease

The organization of chromosomes within the nucleus impacts human disease. Exposure to radiation, chemicals, and other environmental factors can induce double-strand breaks in chromosomal DNA. The cell uses multiple pathways to repair this damage. Nonhomologous end joining is a pathway that joins the broken ends of chromosomes and requires little to no DNA sequence homology. The net outcome of the repair process may be a chromosomal translocation in which segments from two different chromosomes are covalently linked. Given that the repair process involves physical association of the two broken ends, the breakpoints of the translocations that occur are a reflection of the spatial arrangement of chromosomes in the three-dimensional nucleus.

Given the nonrandom distribution of chromosomes within the nucleus, it follows that genes reside in specific positions. A large-scale characterization of gene positions has been undertaken in normal and invasive breast cancer cells during interphase of the cell cycle, the stage in which transcription occurs. The comparative data showed that a small subset of the genes underwent reorganization upon cancer transformation. Interestingly, these genes were not physically linked on the same chromosome. Thus, gene positioning might represent a new marker that could be used to identify cancer cells among a population of normal cells or serve as a means of distinguishing between cancer subtypes.

Conclusions

The astute observations made by early researchers led to the discovery that the nucleus is not a homogeneous collection of confined molecules. Within its spherical structure resides a highly complex organization of chromosomes and protein complexes, each with their assigned three-dimensional position. This organization is imposed by connections with the nuclear envelope and a proposed nuclear substructure. Chromosomes exist in territories that are, to a certain degree, related to the overall gene activity of the chromosome. Genes within a given territory can shift in location upon activation or repression. As a general rule, the nuclear interior is a place of gene activity, whereas the nuclear periphery is generally, but not always, a location of gene silencing. Chromosome and gene positioning is dynamic and can change upon alterations in activity and with disease.

Glossary

Cargo Macromolecular substrate to be transported between the nucleus and the cytoplasm.

Classical nuclear localization signal (cNLS) The most common form of nuclear localization signal comprised of one or two clusters of basic amino acids.

GTPase Protein that binds to and hydrolyzes the nucleotide guanosine triphosphate (GTP).

Heterogeneous nuclear ribonucleoprotein (hnRNP) Abundant poly(A) + RNA-binding protein.

Messenger RNA (mRNA) Class of RNA that carries the information from the DNA to the cytoplasm and serves as the informational blueprint for protein synthesis.

Nuclear export signal (NES) An amino acid sequence within a protein that targets that protein for export from the nucleus.

Nuclear localization signal (NLS) An amino acid sequence within a protein that targets that protein for import into the nucleus.

Nuclear pore complex (NPC) The large proteinaceous channel through which macromolecular cargoes are transported in and out of the nucleus.

Nucleoporins Proteins that make up the NPC.

Ran A small GTPase that regulates the directionality of nuclear transport.

RanGAP Cytoplasmic protein that enhances the GTPase activity of Ran.

RanGEF Nuclear protein that facilitates the nucleotide exchange on Ran.

Ribosomal RNA (rRNA) Class of RNA that serves as a structural and catalytic component of ribosomes.

Transfer RNA (tRNA) Class of RNA that is charged with amino acids to decode the mRNA for protein synthesis.

Transport receptor/karyopherin/importin/exportin The receptors that bind to and recognize protein and RNA cargoes that are transported into or out of the nucleus.

U small nuclear RNA (U snRNA) Small RNAs that participate in splicing.

Nuclear Pores

All transport between the nucleus and the cytoplasm occurs through large protein channels that are embedded in the nuclear membrane. These channels, which are called nuclear pore complexes (NPCs), are composed of proteins referred to as nucleoporins. Small molecules such as water and ions can diffuse through NPCs, but larger cargoes (>40 kDa) such as proteins and RNA require the participation of soluble transport receptors.

Structure

NPCs are large (~30 MDa in yeast and ~60 MDa in vertebrates) structures that span the double membrane surrounding the nucleus and provide a transport channel between the nucleus and the cytoplasm. Many different studies have led to a model for the structure of the NPC (Figure 1). The core of the NPC consists of a cylinder with eightfold rotational symmetry, which perforates the nuclear envelope and surrounds a central, hourglass-shaped channel. In addition to this central channel, there are filaments that extend into the cytoplasm and a basket structure that extends into the nucleoplasm. Cargoes that move through the nuclear pores probably interact first with the peripheral structures, move through the central channel, and are then released into their target compartment.

Composition

Sophisticated biochemical studies have revealed the identity of the nucleoporin proteins (termed Nups) that make up the

NPC. Surprisingly, these studies reveal that both the budding yeast and vertebrate nuclear pores are composed of only approximately 30 distinct proteins that are largely conserved from budding yeast to humans (Figure 2 and Table 1). The NPC is large because most of these pore components are present in 16–32 copies per NPC. Many of these nucleoporins contain a characteristic repeat sequence of phenylalanine glycine (FG) repeats. These FG-repeat nucleoporins line the central channel of the pore and provide the conduit for movement of macromolecules through the pore complex.

Transport Mechanisms: Protein Trafficking

Transport through nuclear pores occurs in both directions, from the nucleus to the cytoplasm and from the cytoplasm to the nucleus. The desired direction of transport generally depends on the cargo to be transported. The cell has developed mechanisms to mark cargoes for transport and regulate the direction of the transport processes.

Targeting Signals

As with most intracellular targeting mechanisms, trafficking between the nucleus and the cytoplasm depends on amino acid sequences within the protein cargoes to be transported. However, unlike other targeting mechanisms such as mitochondrial and endoplasmic reticulum targeting, nucleocytoplasmic trafficking signals are not cleaved and instead remain

an integral part of the protein. This mechanism can allow the cargo proteins to undergo multiple rounds of import and/or export. The nuclear-targeting signal within the cargo protein generally mediates a physical interaction with a soluble nuclear transport receptor, which targets the cargo to the nuclear pore and mediates interactions with nucleoporins to facilitate translocation through the NPC.

Canonical signals for both nuclear protein import and nuclear protein export have been identified. Nuclear import signals are generally termed 'nuclear localization signals'

(NLSs), while signals that target proteins for export from the nucleus are termed 'nuclear export signals' (NESs). Putative NLS and NES signals in candidate proteins are typically identified through computer searches of protein sequences, but it is essential that their function be verified through experimental methods.

Two classes of NLS have been described in great detail: the classical NLS (cNLS) and the proline-tyrosine (PY)-NLS. The canonical cNLS consists of either a single cluster of basic amino acid residues (monopartite) or two clusters of basic amino acid residues separated by a 10-amino acid-linker sequence (bipartite). There is evidence, however, that the linker sequence in functional bipartite cNLS sequences can vary and contain up to 20 amino acids. The monopartite cNLS sequence is typified by the NLS found in the simian virus 40 (SV40) large T antigen (PKKKRKV) and the bipartite cNLS is typified by the nucleoplasmin NLS (KRPAATKKAGQAKKKK). The PY-NLS consists of an upstream basic or hydrophobic region followed by an R/H/KX₂₋₅PY motif. The C-terminal proline and tyrosine residues lend their name to this targeting signal, but there is evidence that other residues including phenylalanine, histidine, and methionine can also function in the final position of a PY-NLS and that the entire signal can accommodate considerable sequence variability due to contributions from multiple-binding regions. Other NLS sequences undoubtedly exist and have even been proposed, but none have been characterized in detail or generalized into predictive consensus sequences. The classical NES is comprised of a series of hydrophobic amino acids, generally leucine, isoleucine, or valine. Numerous

Figure 1 Schematic of the nuclear pore complex (NPC). Left: a schematic of the pore in the plane of the nuclear membrane showing the cytoplasmic filaments and the nuclear basket. Right: a schematic view of the pore looking down from the cytoplasmic face. The eightfold rotational symmetry of the pore is evident.

Figure 2 The nucleoporin proteins or Nups that make up the nuclear pore are highly conserved. A schematic of the nuclear pore with the cytoplasmic side at the top and the nuclear basket at the bottom is shown. The names of the Nups located in each region of the nuclear pore are indicated. The left of the schematic provides the names of budding yeast proteins and the corresponding vertebrate proteins are indicated on the right (see also Table 1).

^aSome Nups share sequence similarity with multiple Nups.

^bA dash (–) indicates that no homolog has been identified.

^cFG, FG repeat domains; ND, not determined, TMH, transmembrane helix.

^dNsp1 (Nup62) is symmetrically located as part of the Nsp1 (Nup62) complex, and also localizes to the cytoplasmic face individually.

variations on this theme have been identified and, thus far, the best consensus sequence for an NES is LxxxLxxLxL; however, the leucines in this motif can be spaced differently and can be substituted with virtually any hydrophobic amino acid.

Transport Receptors

Targeting signals within cargo proteins are recognized by soluble receptors that direct those cargoes to the nuclear pore for transport. In general, these receptors form a family of structurally related molecules that are referred to as importins (for import receptors) and exportins (for export receptors) or as transport receptors or karyopherins. The family of related receptors is generally referred to as the importin β or karyopherin β family. One feature of these transport receptors is that they are modulated in such a way that they bind tightly to their cargo in the compartment where the cargo is picked up; however, following translocation through the NPC to the compartment where the cargo is delivered, the transport receptor undergoes a conformational change that leads to efficient release and delivery of the cargo. This switch in binding affinity is regulated by the small guanosine triphosphatase (GTPase), Ran.

Although most transport cargoes bind directly to their cognate transport receptor, there are examples where an adaptor protein mediates this interaction. The best example of this occurs in nuclear protein import of cargoes bearing a cNLS sequence. The cNLS within these cargoes is recognized by an adaptor protein called importin α or karyopherin α .

The importin/karyopherin α recognizes and binds to the cargo and enters the nucleus as a trimeric import complex consisting of cNLS cargo, importin/karyopherin α , and a conventional transport receptor termed importin/karyopherin β .

Once cargo is released from the transport receptors within the delivery compartment, all the receptors are recycled for subsequent rounds of transport. Import receptors are recycled back to the cytoplasm and export receptors are recycled back to the nucleus. This recycling of receptors ensures that a single receptor can mediate multiple rounds of transport.

The Ran GTPase Cycle

The small GTPase Ran serves as a molecular switch that modulates the directionality of nuclear transport. As with other GTPases, Ran can exist in two forms: bound to guanosine diphosphate (GDP) (RanGDP) or bound to GTP (RanGTP). It is the compartmentalization of these two distinct forms of Ran that regulates interaction between cargo and receptor and imparts directionality on nuclear transport. This compartmentalization is achieved through intracellular separation of the two important regulators of the Ran GTPase cycle. The Ran GTPase-activating protein (RanGAP), which enhances Ran-mediated GTP hydrolysis, is located in the cytoplasm and the Ran guanine nucleotide exchange factor (RanGEF), which facilitates exchange of GDP for GTP on Ran, is located in the nucleus. As RanGAP is in the cytoplasm, any RanGTP that enters the cytoplasm is rapidly converted to RanGDP.

Figure 3 Ran regulates the assembly of import and export complexes. Top: for transport into the nucleus (import), cargoes are recognized in the cytoplasm by an importin/karyopherin β receptor to form an import complex. Once this complex is translocated into the nucleus, it encounters the nuclear RanGTP, which binds tightly to the importin/karyopherin β receptor and causes a conformational change that releases the import cargo. Bottom: for transport out of the nucleus (export), cargoes are recognized in the nucleus by an importin/karyopherin β receptor. However, in contrast to the import complex, the export complex can only form in the presence of RanGTP. Thus, export complexes are obligate trimeric complexes that consist of the export cargo, the importin/karyopherin β export receptor, and RanGTP. Once the export complex is translocated to the cytoplasm, it encounters the RanGAP. In the presence of RanGAP, the RanGTP within the complex is converted to RanGDP and the complex dissociates, resulting in release of the export cargo into the cytoplasm. Hence, by controlling complex assembly and disassembly, different forms of Ran confer directionality on the nuclear transport machinery.

Therefore, the level of RanGDP exceeds the level of RanGTP in the cytoplasm. By contrast, as RanGEF is in the nucleus, RanGDP is rapidly converted to RanGTP and the level of RanGTP is high compared to the level of RanGDP in the nucleus.

The different nucleotide-bound states of Ran regulate the flow of protein cargoes into and out of the nucleus by regulating assembly of import and export complexes (Figure 3). Cargoes to be transported into the nucleus bind to their cognate import receptors in the cytoplasm. These complexes are translocated into the nucleus, where levels of RanGTP are elevated. There, RanGTP binds to the import receptor causing a conformational change that releases the import cargo into the nucleus. By contrast, export cargoes bind to their export receptors only in the presence of RanGTP. Therefore, export complexes are obligate trimeric complexes consisting of the export receptor, the export cargo, and RanGTP. As with import, the export complex is translocated through NPCs to the cytoplasm. In the cytoplasm, the export complex encounters RanGAP and the bound RanGTP is converted to RanGDP. This conversion disassembles the export complex and leads to release of the export cargo into the cytoplasm.

Classical NLS-Mediated Protein Import

The best-understood nuclear transport process is the import of protein cargoes that contain a classical basic NLS (Figure 4). Thus, this process can be used most readily to illustrate the steps that occur when a transport cargo is moved into or out of the nucleus. Historically, nuclear protein import was divided into two steps, docking at the nuclear pore, an energy-independent step, and translocation into the nucleus, an energy-dependent step. Advances in our understanding of the process and the players

now lead us to define at least five distinct steps for import of a cargo that contains a classical NLS: (1) recognition and binding of the cNLS cargo to the importin/karyopherin α -importin/karyopherin β heterodimeric import receptor in the cytoplasm; (2) targeting to the nuclear pore through interactions between the importin/karyopherin β nuclear transport receptor and the nuclear pore; (3) translocation through the pore via transient interactions between importin/karyopherin β and the FG-repeat containing nucleoporins; (4) delivery into the nucleus where RanGTP binds to importin/karyopherin β to cause a conformational change that releases importin/karyopherin α and the cNLS cargo; and (5) recycling of importin/karyopherin α to the cytoplasm in a heterotrimeric complex with an export receptor and RanGTP and recycling of importin/karyopherin β , presumably in complex with RanGTP. Note that the only energy expenditure in this process occurs when the karyopherin proteins are recycled to the cytoplasm and the accompanying RanGTP is hydrolyzed.

Transport Mechanisms: RNA Trafficking

Multiple classes of RNAs, including messenger RNA (mRNA), transfer RNA (tRNA), micro-RNA (miRNA), ribosomal RNA (rRNA), and U small nuclear RNA (U snRNA), are transcribed within the nucleus and then transported to the cytoplasm. As compared with proteins, RNAs require extensive processing before they reach their mature form and are ready to exit the nucleus. This requirement means that RNA export is intimately linked to RNA processing within the nucleus.

The export of tRNA, U snRNA, miRNA, and rRNA follows pathways analogous to nuclear protein export. In each case, the

Figure 4 Model for classical NLS-mediated protein import into the nucleus. The best-understood transport mechanism is that of classical nuclear protein import, which is mediated by importin/karyopherin β and the cNLS-binding adapter, importin/karyopherin α . This process can be divided into at least five distinct steps as shown in the model: (1) recognition and binding of the cNLS cargo to the importin/karyopherin α -importin/karyopherin β heterodimeric import receptor in the cytoplasm; (2) targeting to the nuclear pore; (3) translocation through the pore; (4) delivery into the nucleus; and (5) recycling of importin/karyopherin α and importin/karyopherin β to the cytoplasm.

RNA is recognized either directly or indirectly by an importin/karyopherin β family nuclear transport receptor and exported to the cytoplasm in a Ran-dependent manner. mRNAs are exported to the cytoplasm as messenger ribonucleoprotein complexes through a mechanistically distinct pathway.

tRNA Export

tRNAs are synthesized in the nucleus by RNA polymerase III (Pol III) and undergo a number of maturation steps such as splicing, modification of the 5' and 3' termini, and aminoacylation prior to export to the cytoplasm where they are required for protein translation. Mature tRNAs are preferentially recognized in the nucleus by the importin/karyopherin β receptor, exportin-t/Los1/PAUSED, and are exported in complex with RanGTP. The NES signals in tRNAs require a specific 3' overhang and secondary and tertiary structures within the RNA to form, ensuring that only fully processed tRNAs are exported to the cytoplasm. Interestingly, Los1 and PAUSED are not essential in *Saccharomyces cerevisiae* or *Drosophila melanogaster*, respectively, suggesting that parallel pathways for tRNA export likely exist. Two additional importin/karyopherin β family members, Msn5, a receptor mainly involved in export of proteins that regulate transcription, and exportin-5, a receptor mainly involved in miRNA export, have been implicated in these alternative pathways.

miRNA Export

miRNAs are short, noncoding RNA sequences that are involved in posttranslational regulation of gene expression. They bind

complementary sequences in target mRNAs, resulting in translational silencing. The primary transcripts for miRNAs are transcribed by Pol II or Pol III and contain a stem-loop that is excised in the nucleus by an RNase called Drosha. This stem-loop, called pre-miRNA, is exported to the cytoplasm by the importin/karyopherin β , exportin-5, in complex with RanGTP. Following RanGTP hydrolysis, the freed pre-miRNA is cleaved by an RNase called Dicer to eventually form a single-stranded miRNA, which is incorporated into the RNA-induced silencing complex.

U snRNA Export

Many small nuclear RNAs, such as U snRNAs, are involved in mediating or regulating posttranslational RNA-processing events such as splicing. Most of these RNAs are transcribed in the nucleus by Pol II or Pol III as pre-snRNA, then capped on the 5' end and exported to the cytoplasm. Once in the cytoplasm, snRNAs associate with the protein components of small nuclear ribonucleoproteins and are reimported into the nucleus to perform their function. Export of U snRNA is mediated by the classical protein export receptor, Crm1/exportin-1, but requires an adaptor consisting of the cap-binding complex and the NES-containing protein, PHAX.

rRNA Export

Eukaryotic ribosomes, which translate mRNAs into proteins, are comprised of a large (60S) subunit and a small (40S) subunit. These subunits are generated in the nucleolus and each contains a number of rRNAs and up to ~50 proteins.

The 60S subunit is exported from the nucleus by Crm1/exportin-1 in a RanGTP-dependent manner. The leucine-rich NES recognized by Crm1/exportin-1 during the 60S subunit export is provided by the adaptor Nmd3, a *trans*-acting factor that associates with the 60S subunit during biogenesis. Due to its size, it is likely that other transport factors, such as Rrp12 or Mtr2 (a protein involved in mRNA export), are also involved in the export of the 60S subunit. Export of the 40S subunit is less well understood, but Crm1/exportin-1 and the Ran cycle are required. Several subunit components and assembly factors have been suggested to provide the NES for 40S subunit export, but no definitive mediator or adaptor has been identified.

mRNA Export

mRNAs are transcribed by Pol II in the nucleus, capped at the 5' end, spliced, and polyadenylated at the 3' end prior to export to the cytoplasm for translation. During these modification steps, various processing factors are recruited to the pre-mRNA and many of these proteins remain bound to the transcript, providing signposts that proper processing has occurred. Many of these heterogeneous nuclear ribonucleoproteins or RNA-binding proteins shuttle between the cytoplasm and the nucleus and escort the poly(A) + mRNA as it is exported through the NPC. Therefore, mRNAs are not exported to the cytoplasm as naked nucleic acids, but rather as RNA–protein complexes. It is generally agreed that mRNA export machinery recognizes signals within the proteins of these complexes rather than the mRNA itself.

Several export receptors have been implicated in the export of at least a subset of mRNA transcripts. The heterodimeric Mex67-Mtr2 (TAP-p15 in humans) complex can bind directly to mRNA, but relies on recruited mRNA-binding adaptor proteins such as Yra1/Aly/REF or members of the TREX complex to mediate interaction with mRNA. Alternatively, a small subset of cellular mRNA transcripts containing AUI-rich elements, which recruit NES-containing adapter proteins, are exported by the classical NES receptor, Crm1/exportin-1. Export of

intron-containing human immunodeficiency virus (HIV) transcripts from the nucleus is also dependent on Crm1/exportin-1 and is mediated by the HIV protein Rev.

Glossary

Nucleolus organizer A genetic locus containing genes for ribosomal RNA.

Perinucleolar compartment A discoid, cap-like structure situated on the surface of nucleoli in most malignant cells.

Proteomics An emergent field of protein sequence determination in complex mixtures, based on a

high-resolution analytical method in which the protein components of a subcellular complex or organelle, first separated by electrophoresis or liquid chromatography, are proteolytically cleaved (usually by trypsin) into fragments that are then resolved by matrix-assisted, laser-desorption ionization time-of-flight mass spectrometry.

Background

The nucleolus was one of the earliest intracellular structures (and the first within the nucleus) to be observed by microscopy, around 1860. Throughout the early twentieth century, cytologists were struck by the consistent presence of nucleoli inside the nuclei of virtually all cells examined, although the number and shape of nucleoli were quite variable (Figure 1). In the 1930s, it was discovered that the formation of the nucleolus is determined by a distinct genetic locus. This genetic element, termed the nucleolus organizer, was found in the 1960s to consist of repeated genes for ribosomal RNA (rRNA). It is an interesting historical fact that the rRNA genes were not only the first ones from eukaryotes to be observed at high resolution in the electron microscope, but also the first genes to be physically isolated, well before the advent of recombinant DNA techniques.

Although a considerable amount of cytochemical and ultrastructural research had been done on nucleoli up through the 1950s, a major advance occurred when they were first isolated by cell fractionation in the mid-1960s. This opened the door to the investigation of their protein and RNA components, and accelerated the study of rRNA synthesis and processing.

Structure

Although the ultrastructural (electron microscopic) appearance of nucleoli is highly variable, a tripartite organization is generally observed. Fibrillar centers (FCs) are one or more rather small foci within a nucleolus that have a distinctive appearance. Each of these FCs is surrounded (in three dimensions) by a typically much larger zone, called the dense fibrillar component (DFC). The remainder of the nucleolus, or at least most of the remainder, displays a distinctly more granular appearance, and is, thus, called the granular component (GC).

Functional Organization

The tripartite ultrastructural landscape of the nucleolus has been functionally defined (Figure 2). The FCs are the zones where the active rRNA genes themselves are located. The nascent transcripts

of pre-rRNA extend out into the juxtaposed DFC, which also contains intermediate RNA species in the rRNA-processing pathway. Also present in the DFC are numerous (100–200 or more) small RNA species (and their associated proteins) that serve as guide RNAs for the site-specific modification (2'-O-ribose methylation and pseudouridine formation) of many internal nucleotides in pre-rRNA. The GC consists of more mature, assembled ribosomal particles. It is not yet entirely clear whether certain stages of ribosome maturation are sharply restricted to the DFC or the GC or instead have some degree of overlap between them.

Amplified Nucleoli and Missing Nucleoli

One of the most dramatic aspects of the biology of the nucleolus is its selective amplification in the oocytes of certain organisms. In these cells, the rRNA genes are amplified into a large number (typically thousands) of extrachromosomal copies, which form supernumerary nucleoli. Through their activity, the growing oocyte builds up a large reservoir of maternal ribosomes to sustain early embryonic development. Amplified nucleoli are found in the oocytes of several phyletic groups, but have been most extensively studied in urodele and anuran Amphibia (salamanders and frogs).

One of the ways the function of the nucleolus in ribosome synthesis was first revealed was by an elegant experiment that involved a frog mutant in which one chromosomal set of rRNA genes is missing. Half the oocytes of females that are heterozygous for this mutation have no rRNA genes whatsoever and, consequently, cannot form amplified nucleoli, nor can anucleolate embryos descended from them synthesize new ribosomes. Accordingly, these embryos die at a time during development when the maternal supply of ribosomes becomes limited. This experiment is one of the classics in the field of eukaryotic gene expression.

Clinical Connections

Two aspects of the nucleolus are significant clinically. For many years, pathologists have used nucleolar morphology

Figure 1 Phase-contrast micrograph of a portion of a living HeLa (human cervical carcinoma) cell. The dark, spherical objects within the nucleus are the nucleoli. This micrograph was taken by Laura Lewandowski in the author's laboratory. Magnification approximately $\times 3000$.

and number as an important guide in the diagnostic classification of certain malignancies. In addition, a specialized structure called the perinucleolar compartment (PNC) sits as a cap-like disk on the surface of the nucleoli in most malignant cells (both tumor cell lines and actual patient biopsies). The PNC seems to be involved in RNA metabolism, and contains a set of small RNAs that are transcribed by RNA polymerase III. However, its possible causative relationship to malignancy is not known.

The Plurifunctional Nucleolus

Since the 1990s, a number of clues have begun to suggest that the nucleolus may have functions beyond ribosome synthesis. One line of evidence consists of the observation in nucleoli of various molecules that have no known connection with ribosome biosynthesis. For example, several proteins related to mitogenic cell signaling and cell-cycle progression have been found in nucleoli, although these various observations have not yet been drawn together into a coherent framework. In budding yeast, the nucleolus of interphase cells contains a complex that is released and promotes a late stage of mitosis after the nucleolus breaks down, but whether this complex has some role within the interphase nucleolus as well is not known. The fact that so many of the various ribosome-unrelated molecules and complexes that are increasingly being observed in the nucleolus are related to cell growth is quite intriguing, and this is an important area for future work.

It has also become clear that the life cycle of certain viruses involves the nucleolus in some way. For example, in the replication of the human immunodeficiency virus, certain forms of viral messenger RNAs are associated with the nucleolus during a particular stage in the infectious cycle.

Figure 2 A schematic diagram illustrating the relationships of the three major components of the nucleolus. An FC contains the active rRNA genes (blue) with the nascent transcripts of pre-rRNA (red) extending into the surrounding DFC, embedded in the GC. See text for further details. Reproduced from Huang S (2002) Building an efficient factory: Where is pre-rRNA synthesized in the nucleolus? *Journal of Cell Biology* 157: 739–741, with permission from Rockefeller University Press.

However, the functional significance of this and other observations of viral connections with the nucleolus are not presently known.

A third nonribosomal function of the nucleolus is its likely participation in the biosynthesis of the signal-recognition particle (SRP). The SRP is an RNA–protein complex that ensures the topologically correct synthesis of membrane and secreted proteins. Both the RNA component of the SRP and some of the SRP's protein components are present in the nucleolus in yeast, amphibian oocytes (i.e., in the amplified nucleoli), and mammalian cells, suggesting that this translation-related RNA–protein complex originates in the nucleolus, as do the ribosomes themselves.

Current Trends and Conclusion

At the present time, studies on the nucleolus are being conducted by nucleolar specialists on the one hand, and by an increasing number of cell biologists on the other, who are encountering a nucleolar connection in their work. A nucleolar protein called nucleostemin has been implicated in the biology of embryonic stem cells, and a reorganization of the nucleolus in donor somatic cell nuclei appears to be a key factor in the cloning of mammalian animals. Meanwhile, on the analytical front, proteomics studies of purified human nucleoli have identified ~ 350 proteins that are highly enriched in the isolated fraction (Figure 3). Many of these proteins have no obvious relationship to ribosome biosynthesis. One interesting possibility is that perhaps all of these apparently nonribosome-related nucleolar components are indeed related to ribosome biosynthesis after all, not in the constitutive pathway of ribosome synthesis itself (the classical model), but as regulatory components of cellular growth control circuits that intersect in the nucleolus and, thus, with the biogenesis of the protein synthesis machinery (a neoclassical model).

Figure 3 Relative occurrence of various classes of proteins in nucleoli purified from HeLa cells, as determined by proteomics. Glossary

DNA polymerase A protein or protein complex which synthesizes a daughter strand of DNA using a parental strand as a template.

Helicase A protein, which actively separates the two strands of DNA using the energy of ATP hydrolysis.

Nucleotide excision repair (NER) A highly conserved multistep process in which several protein machines identify and remove bulky damage from DNA using a dual incision mechanism.

SOS response A number of DNA metabolism genes controlled by the LexA repressor, which is cleaved during genotoxic stress.

uvr genes Genes encoding subunits of NER proteins, which confer sensitivity to killing by ultraviolet light.

Zinc finger A DNA-binding motif consisting of a molecule of zinc bound to four cysteines found in many DNA-repair proteins.

This article is dedicated to Lawrence (Larry) Grossman, PhD, 1924–2006 who was the University Distinguished Service Professor of Biochemistry in the Department of Biochemistry and Molecular Biology in the Johns Hopkins Bloomberg School of Public Health. He was an inspiration, friend, and a 'worthy opponent'. DNA repair is intrinsic to the evolution of life, and organisms have evolved a large number of complex systems to ensure the integrity of their hereditary material. DNA constantly undergoes chemical modification as a result of its intrinsic chemical instability, as well as endogenous and environmental stresses. The most versatile DNA repair mechanism is nucleotide excision repair (NER), first discovered in *Escherichia coli* in 1964 independently by Setlow and Carrier and Boyce and Howard-Flanders. This bacterial system, like its eukaryotic counterpart, has a very broad spectrum of damage recognition and operates according to the same basic principles in all organisms:

1. repair proteins form macromolecular assemblies in order to locate and activate damage utilizing a number of adenosine triphosphate (ATP)-hydrolysis-driven nucleoprotein rearrangements;
2. the DNA is incised on both sides of damage; and
3. the incised fragment is displaced with concomitant resynthesis followed by ligation.

NER is coupled to other cellular processes, notably, transcription. The sequencing of the complete genomes of over 100 different bacterial species indicates that the NER system is a highly conserved process.

UvrABC Endonuclease

The NER pathway consists of five basic steps: damage recognition, incision, excision, repair synthesis, and ligation. In most bacteria, the first steps of this process are carried out by an ensemble of three proteins encoded by the *uvrA*, *uvrB*, and *uvrC* genes in an ATP-dependent series of reactions. During the

initial characterization of these proteins, the name of this system was shortened to 'UvrABC endonuclease', which makes both the 5' and 3' incisions to a lesion in a 'dual incision' reaction (Figure 1). The UvrABC endonuclease possesses a broad spectrum of substrate specificity and is capable of acting on a wide variety of unrelated DNA damage (Table 1).

Genetics and Evolutionary Conservation of uvr Genes

It was photobiologists who discovered NER from analyses of ultraviolet (UV) radiation survival curves in some bacterial, most notably *E. coli*. Rather than observing a first-order decline in survival of cells as a function of UV dose, there was a shoulder in the survival curves at lower doses. Some *E. coli* mutants, which lacked this shoulder, were sensitive to low doses of UV and were isolated. All these mutants map at one of three loci on the *E. coli* chromosome designated *uvrA* (92 min), *uvrB* (17 min), and *uvrC* (41.5 min), and, are hence, unlinked genes. In species of *Bacillus*, the *uvrA* and *uvrB* genes are within 50 bp of each other on the chromosome.

The *uvr* genes were first cloned, sequenced, and amplified from *E. coli*, which led to a greater understanding of the roles of three proteins in the process of damage recognition and incision. Subsequently, large-scale sequencing efforts have revealed that *uvr* genes are highly conserved among the bacteria species.

uvrA

uvrA is one of a series of genes collectively referred to as SOS genes, which are induced to increased levels of transcription by agents that cause DNA damage. A specific binding site for the LexA repressor protein specific for the operator promoter region of the *uvrA* gene (the so-called LexA box or SOS box) has been identified. Sequence analyses reveal that the *uvrA* gene (2.82 kbp) translates into 940 amino acids ($M_r = 103\,874$ Da) and contains two ATP-binding motifs, two zinc-finger motifs, and a helix–turn–helix motif.

Figure 1 Nucleotide excision repair pathway in bacteria. Dimeric UvrA protein (light green and pink) (PDB ID:2R6F) hydrolyzes both ATP and GTP, and forms a complex with UvrB, orange (PDB ID: 2FDC). During damage detection, the UvrA₂B₂ complex (PDB ID for the contact interface:3FPN) first searches for damage-induced distortions in the DNA helix which are recognized by UvrA. DNA containing a benzo[a] pyrene diol epoxide-N₂-guanine adduct is shown in green. This activates the ATPase activity of UvrB and UvrA transfers the damaged DNA to UvrB. During damage verification, the β -hairpin of UvrB (shown in purple) inserts between the two strands of DNA, clamping the damaged strand forming a stable pre-incision complex. Binding and hydrolysis of ATP by UvrB are essential for recruitment of UvrC. The N-terminal endonuclease domain of UvrC (PDB ID:1YCZ) initiates the cut 4–5 nucleotides 3' to the damaged site followed by the 5' cut by C-terminal endonuclease domain of UvrC (PDB ID:2NRR) 8 nucleotides away from the lesion (both domains are shown in dark blue). Working together UvrD (red) (PDB ID:2IS1) unwinds the DNA and releases the oligonucleotide containing the lesion, while DNA polymerase I (turquoise) (PDB ID:2HHQ) synthesizes the missing strand (shown in yellow). Finally, DNA ligase I, dark gray (PDB ID:1DGS), seals the nick and completes the repair patch. All the protein structures are displayed using the α -carbon trace showing β -sheets and α -helices, with the van der Waal surface shown in light gray. The UvrA₂B₂ complex was created from three individual structures of UvrB (PDB ID:2FDC), UvrA (PDB ID:2R6F), and the contact interface of UvrA and UvrB (PDB ID:3FPN). The UvrB–DNA complex was modified from the UvrB–DNA co-crystal structure (PDB ID:2FDC).

Table 1 Range of substrates of the bacterial NER UvrABC system

Type	Lesion	UvrABC	ΔM_r	Properties
Single base modification	Thymine glycol	++	+34	
	Dihydrothymine	0	+2	
	Benzo[a]pyrene adduct	+++	+171	T_M lowered
	Anthramycin adduct	+++	+191	T_M elevated
	Cross-linked triple strand	+ [72]	~+3000	
	O^4 -alkyl thymine	+	+14	
	O^6 -methyl guanine	+	+14	
	N^6 -methyl adenine	0	+14	
	Psoralen adduct	+++	+185	Positive kink
	Base removed (AP site)	+	~-130	
Cross-links, intra-strand	<i>cis</i> -Pt adduct	+++	+227	Negative kink
	Pyrimidine dimer	++	0	
	6-4 photoproduct	+++	0	
	<i>cis</i> -Pt adduct	++	+227	
Cross-links, inter-strand	Nitrogen mustard adduct	+	+69	
	Psoralen bisadduct	+++	+185	Unwound
	dsDNA	0	0	
Natural bases	A-tracts	0	0	Bent
	Mismatches, loops	0 ^a	0	
	Caffeine complex	—	+194	Intercalator
Noncovalent modifications	Ditercalinium complex	++ ^b	+500	Bisintercalator

^aSome mismatches are recognized with very low efficiency (<1%).

^bFutile cycle of spurious repair and subsequent formation of the complex at another site.

uvrB

The *uvrB* gene is also a member of the SOS regulon and is inducible by DNA damage. The gene is transcribed from two overlapping promoters called P1 and P2. A LexA protein-binding site is present in the P2 promoter region. Transcription from P2 is inhibited by LexA repressor protein, while that from P1 is unaffected. Sequence analysis revealed that the *uvrB* gene is 2019 bp, which translates into 673 amino acids (76.6 kDa). The *uvrB* gene product has a consensus Walker-type A nucleotide-binding motif, helicase motifs II–VI as well as coiled-coil consensus sequences.

uvrC

In contrast to *uvrA* and *uvrB*, *uvrC* is not inducible by DNA damage and is not a member of the SOS regulon, although its cellular location is altered during SOS. The sequence analysis shows that the size of *uvrC* is 1830 bp encoding a polypeptide of 610 amino acids (66 kDa).

Cho

It was quite surprising that a new UvrC homolog, Cho, could be discovered in an organism for which the complete genome sequence was known since 1997. The gene encoding Cho was found to be UV-inducible by Hanawalt and Brown using a high-density DNA microarray. Careful inspection of this gene revealed homology to the T_{ev}-homing endonucleases and also the N terminus of UvrC. Goosen and co-workers cloned and overexpressed the Cho protein, and found that the Cho protein will incise a DNA adduct at the tenth phosphodiester bond 3' to the damaged site. This cutting at a distance was shown to

help incise at bulky lesions, which might otherwise block the normal UvrC 3' incision. They also found that UvrC can complete the incision process by efficient cleavage 5' to the 3' incised adduct. Cho is rather rare in the bacterial kingdom (Figure 2).

Properties of UvrA, UvrB, and UvrC Proteins

UvrA

The UvrA protein is a DNA-independent ATPase that binds DNA and is a member of the ABC transporter superfamily characterized by dual ATP-binding sites. Soon after UvrA was sequenced, it was noticed that the gene probably arose through multiple duplication events in which a four-cysteine zinc finger was placed between the Walker type A and B nucleotide-binding motifs. Site-directed mutagenesis studies show directly that UvrA has an ATPase activity located in a region centered at lysine residues of two Walker type A nucleotide-binding motifs. UvrA also hydrolyzes guanosine triphosphate (GTP). ATPase activity of UvrA is modulated by DNA. High concentrations of UvrA protein and the binding energy of ATP (or poorly hydrolyzable ATP- γ -S) favor dimerization of the protein. UvrA dimers are DNA-binding species. The binding of UvrA to undamaged DNA is 10^3 – 10^4 -fold weaker than to the damaged one. The specificity for damaged DNA is abolished by ATP- γ -S, while it enhances nonspecific binding. The dissociation rate for UvrA from damaged sites is fast in the presence of ATP. ATP hydrolysis increases the specificity of binding to the damaged DNA, but lowers the equilibrium-binding constant by stimulating dissociation. The crystal structure of a UvrA dimer by Verdine and co-workers indicated that each UvrA

Figure 2 Phylogenetic tree of UvrC and Cho in various bacterial species. Phylogenetic tree of UvrC and Cho homologs. Homologs were identified in complete or nearly complete genomes by blastp or blastx searches. Protein sequences were aligned using clustalx. Bootstrap values, a measure of statistical support for particular groupings of genes to the right of the number, are shown on the tree when >40%. Reproduced from Van Houten B, Eisen JA, and Hanawalt PC (2002) A cut above: Discovery of an alternative excision repair pathway in bacteria. *Proceedings of the National Academy of Sciences of the United States of America* 99(5): 2581–2583.

Figure 3 Crystal structure of UvrA. The UvrA dimer structure (PDB ID 2R6F): the UvrB-binding domain is shown in orange. For the first nucleotide-binding domain (NBDI), the Walker A and Q loop are shown in magenta; the Walker B, H loop, and signature sequence are shown in red. For the NBDII, the Walker A and Q loop are shown in cyan, the Walker B, H loop, and signature sequence are shown in blue. The Zn ions and ADP molecules are shown as CPK models.

monomer contains three zinc atoms per molecule, at least one of which is required for DNA binding (Figure 3). Van Houten and colleagues have shown that the C-terminal zinc-finger of UvrA is absolutely essential for damage recognition, but not DNA binding. The ATP-binding sites are created by intramolecular interaction of Walker A from one motif with the other Walker B motif.

UvrB

The purified protein has no detectable ATPase activity, although it binds ATP with a $K_d \sim 1$ mM. However, ATPase activity is observed when UvrB interacts with UvrA in the presence of DNA. This dramatic appearance is due to activation of the cryptic ATPase when UvrB forms an UvrAB–DNA complex. When UvrB is proteolyzed in a specific region of the C terminus, the resulting ~ 70 -kDa protein is referred to as UvrB*. The ‘cryptic UvrB ATPase’ functional in UvrB* is activated by single-stranded DNA or chaotropic salts. UvrB can bind to double-stranded DNA only in the presence of UvrA, and binds to single-stranded DNA with a K_d in the micromolar range. The amino acid sequence of the UvrB protein shows homology with two limited stretches of the sequence of the UvrC protein. Three groups have independently solved the crystal structure of UvrB. The structure has revealed that UvrB is folded into four separate domains (Figure 4). Domain 1a includes four helicase motifs: Ia, Ib, II, and III that are required for ATPase activity.

Figure 4 Structure of UvrB. The UvrB structure (PDB ID 2FDC): domain 1a is shown in yellow, 1b in green. Domain 2 is labeled as UvrA interacting domain and shown in magenta. Domain 3 is shown in red, and a separate domain 4 peptide structure is shown in gray. The β -hairpin motif in domain 2 is shown in cyan. ATP is shown in dark blue. UvrB belongs to the helicase superfamily II with seven helicase motifs in domain 1a and domain 3. Below the structure, the sequence of each protein is indicated and color coded as in its respective structure.

Domain 2 is important for UvrA interaction and domain 3 contains helicase motifs, IV, V, and VI. Sandwiched between domains 1a and 1b is an important β -hairpin motif which is believed to provide important DNA contacts. Further details of the UvrB structure and how it provides function are discussed below.

UvrC

UvrC is a single-stranded DNA-binding protein and binds to it with a relatively high affinity. UvrC is a catalytic subunit of the UvrABC endonuclease. Mutations in the C-terminal region of UvrC are extremely sensitive to UV and defective in 5'-incision activity. The 314 C-terminal amino acids of UvrC are sufficient to support dual incision of damaged DNA by the UvrABC endonuclease. UvrC protein associates with a UvrB–DNA complex at damaged site. Recently, the C-terminal part of UvrC was solved by multidimensional nuclear magnetic resonance and shown to consist of two helix–hairpin–helix (HhH) motifs as predicted previously. Kaptein and co-workers found that this C-terminal region of the protein bound avidly to double-strand/single-strand junctions like those found in bubble substrates containing more than six unpaired bases. Interestingly, this is exactly the number of base pairs believed to be unwound during the formation of the UvrB–DNA complex. Most recently, Kisker and colleagues have determined the crystal structure of the N-terminal domain responsible for the 3' incision and the C-terminal domain responsible for the 5' incision (Figure 5).

Figure 5 Structure of UvrC nuclease domains. The two distinct endonuclease centers of UvrC (PDB IDs:1YD5, 2NRR): the N-terminal GIY-YIG family nuclease domain is shown in blue and the residues which are essential for the cleavage are labeled. The metal and surrounded water molecules are shown as a CPK model. The C-terminal endonuclease domain is shown in red and the tandem HhH domain is shown in green. Residues that are necessary for the 5' incision are labeled.

Damage Recognition and Incision

The broad substrate specificity of the UvrABC endonuclease is achieved through a complex molecular mechanism (Figure 1) identifying some general changes in DNA conformation and dynamics rather than chemically modified bases *per se*.

Molecular Mechanism of Damage Recognition

Molecular recognition proceeds through a series of coordinated Uvr protein-protein and nucleoprotein intermediates characterized by different composition and architecture.

UvrA dimerization

UvrA forms a dimer in solution with apparent $K_d \sim 10^{-8}$ M. Nucleotide (ATP) binding to UvrA drives UvrA dimerization, whereas the hydrolysis of ATP or the presence of adenosine diphosphate (ADP) drives monomerization. The UvrA dimer is the active form in binding to undamaged or damaged DNA. The formation of a dimer results in a conformational change of the UvrA protein. UvrA is believed to recognize overall changes in the structure of the DNA helix, and has been found to bend the DNA by about 55° upon binding and unwind the DNA by as much as 3 bp upon DNA binding.

UvrA₂B₂ complex in solution

The purified UvrA protein associates in solution with UvrB protein (domain 2) in an ATP-dependent manner. The N-terminal region of about 150 amino acids of UvrA are involved in this interaction (Figure 3). UvrB has two UvrA-binding sites: one within amino acids 115–250 and another within C-terminal amino acids 573–673. However, UvrB* which lacks these C-terminal amino acids can also bind UvrA in solution. The apparent stoichiometry of the UvrA–UvrB complex in solution is UvrA₂UvrB₁.

UvrA₂–DNA binding

The UvrA dimer binds both damaged and undamaged DNA. ADP decreases the UvrA-binding affinity two- to threefold and ATP is not required for the specific binding to a damaged site. ATP- γ -S quantitatively inhibits the specific binding while enhancing nonspecific binding. The equilibrium constant for nonspecific binding of UvrA is $(0.7\text{--}2.9) \times 10^5 \text{ M}^{-1}$. The apparent binding affinity of UvrA₂ to damaged DNA is in the range $0.07\text{--}1.0 \times 10^9 \text{ M}^{-1}$, depending on the damage type. However, affinity of UvrA₂ to damage does not generally correlate with the efficiency of the entire incision reaction.

UvrA₂B₂–DNA complex

This complex provides for more productive damaged DNA-binding intermediates than UvrA dimer. Binding of UvrA₂B₂ to DNA results in locally unwound undamaged-DNA between 180° and 220° . Furthermore, it has been proposed that the DNA is wound around the UvrB molecule. The formation of the UvrA₂B₂–DNA complex results in a multifold stimulation of ATPase activity apparently through activation of a ‘cryptic’ ATPase of UvrB. Using atomic force microscopy, Goosen and co-workers have shown that UvrA and UvrB can form UvrA₂UvrB₂ complex on DNA. Van Houten and colleagues using single-molecule fluorescence has also shown that the UvrA dimer can serve as a scaffold for binding two UvrB molecules independently. Once the UvrAB complex actively engages the damage, UvrA (and possible one molecule of UvrB) dissociates leaving a long-lived stable UvrB–DNA complex.

Formation of the UvrB–DNA intermediate

Previous work by Grossman and co-workers have suggested that the UvrAB complex can track along the DNA helix using a limited helicase activity to create waves of negative and positive supercoiling behind and in front of the damaged site, respectively. This is consistent with the helicase fold of UvrB (shown in Figure 4). However, work from both the Rupp and Van Houten laboratories have argued that the UvrAB complex cannot dissociate damaged DNA strands even as small as 26 bases, and that the formation of the UvrB–DNA complex leads to a destabilization of the DNA helix. However, neither UvrB by itself nor in complex with UvrA can unwind long tracks of DNA, which is a typical property of proteins with true helicase activity. A recent study by Kad and Van Houten using single-molecule fluorescence of UvrA and UvrB labeled with quantum dots has shown that UvrA searches for DNA damage using a three-dimensional search, and can hop several microns from DNA duplex to DNA duplex. Surprisingly, the addition of UvrB

to UvrA changes the searching mode to one-dimensional sliding on DNA. Thus, UvrB is not only important for damage verification, but also changes the search mode for damage from three dimensions to one-dimensional sliding, rapidly increasing the rate of damage recognition.

Damage-Sensing Mechanism: Padlock Model of Damage Recognition by UvrB

The UvrABC endonuclease does not recognize a specific chemical group or structure in the damaged nucleotide nor does it, in all likelihood, solely recognize a specific backbone deformity in the duplex induced by the varied and unrelated genotoxic chemicals (Table 1). Initial damage recognition may occur through direct UvrA–DNA interactions. This triggers structural changes of the preceding UvrA₂B₁–DNA complex, so that UvrA₂ dissociates, while UvrB is loaded onto a damaged site. Even though the cocrystal structure of the UvrB–DNA complex has not yet been solved, this complex has been observed in footprinting experiments by electron microscopy and gel mobility shifts and the complex is isolated by gel filtration. The formation of this complex requires ATP hydrolysis by both UvrA and UvrB and occurs after the recognition of a damage site by the UvrAB complex. As noted above, Goosen and co-workers have shown that the formation of the UvrB pre-incision complex at damaged sites results in a conformational change of both UvrB and DNA. The DNA molecule in this complex is kinked and the DNA wrapped around the UvrB molecule. Helicase motifs and the β -hairpin motif of UvrB seem to play a role in UvrB–DNA binding at damaged sites (Figure 4). The rate of UvrB loading to DNA is low ($k_{on} = 6 \cdot 10^{-4} \text{ M s}^{-1}$), suggesting that this step may be limiting for damage-specific incision of DNA. Kisker and co-workers have proposed a padlock model of UvrB binding to DNA to help reconcile the earlier helicase-unwinding model of Grossman with the known helicase fold of UvrB. In this model, the UvrAB complex uses the UvrB ATPase to make limited motion along the DNA, causing transient opening and closing of the DNA, in which it is believed that the β -hairpin is inserted through the helix. If a DNA lesion is encountered by UvrB, there is a conformational change in the protein–DNA complex leading to the release of UvrA. In this precision complex, UvrB is believed to lock down the damaged between the β -hairpin and the wall of domain 1B (Figure 6). In this locked padlock model, the damaged strand wraps in front of the β -hairpin and the hydrophobic tyrosine side-changes at the base of the β -hairpin are believed to bind to or facilitate the damaged nucleotide to flip out of the DNA helix. In this locked-down conformation, ATP binding is believed to lead to a large motion of domain 3 which clamps down on the DNA, resulting in further deformation of the DNA helix leading to strained structure that is recognized by UvrC.

Dual Incision

The binding of UvrC to the pre-incision UvrB–DNA complex results in the incision of DNA on both sides of the lesion in the damaged strand. DNA sequence context and the type of

Figure 6 Hypothetical model of UvrB–DNA complex showing proposed damage-recognition pocket. Domains 1b and 3 are indicated as in Figure 4. The proposed conformation of DNA is shown as phosphate backbone in orange with the damaged strand extending under the β -hairpin which is depicted in cyan.

damage affect the precise location of the 5' and 3' incision sites. Usually, it occurs at the 8th phosphodiester bond 5' to the damage and 4th or 5th phosphodiester bond 3' to the damage. The C-terminal coiled-coil motif of UvrB (amino acids 636–668) and the N-terminal homologous regions of UvrC (amino acids 214–239) are required for the formation of UvrBC complex (Figure 5). Site-directed mutagenesis of the UvrC and UvrB proteins has led to the conclusion that the incision process is not a concerted one. The 3' incision is affected by the N terminus of the UvrC protein, and this incision precedes the 5' nicking, catalyzed by the C-terminus of UvrC protein. There is a conformational change of UvrBC–DNA complex following 3'-incision. The C-terminal region of UvrC (amino acids 555–610) is involved in DNA binding and 5'-incision. Dual incision *per se* does not require ATP hydrolysis; ATP- γ -S can substitute ATP during this step.

Postincision Steps

Following dual incision, the UvrBC complex remains bound to damaged DNA. As a result of the stability of the postincision complex, UvrABC endonuclease does not turnover in an *in vitro* system, which is biochemically reconstituted with only Uvr proteins. Restoration of the DNA primary structure and integrity as well as turnover of the Uvr proteins is accomplished in a series of postincision steps, which require products of two additional genes, *uvrD* and *polA*.

UvrD

Its gene maps at 84 min of *E. coli* chromosome. UvrD + is a part of the SOS regulon and is induced by DNA damage. The product of this gene is a 3'-5' DNA helicase II – a 75-kDa protein, which is a DNA-dependent ATPase. DNA helicase II is required for the removal of incised damage as a 12–13-mer oligonucleotide fragment. It also effects the release of UvrC protein, but not UvrB from the postincision complex.

PoiA

Its gene maps at 85 min of *E. coli* genetic map. It encodes a 109-kDa protein, DNA polymerase I. The UvrB protein is not displaced by DNA helicase II and remains bound to gapped DNA. In the presence of deoxyribonucleoside-5'-triphosphates, DNA polymerase I catalyzes repair synthesis, resulting in the filling in of the gap and displacement of the UvrB protein. The size of *in vitro* repair patch is usually ~12 nucleotides in length. Molecular interactions of Uvr proteins, DNA helicase II, and DNA polymerase I during postincision events are not presently known. *E. coli* strains, deficient in *uvrD*⁺ and *polA*⁺, are usually significantly less sensitive to the killing effects of UV radiation than Uvr-deficient strains, indicating their auxiliary role in repair. DNA ligase completes NER by catalyzing joining of the last 3'-nucleotide of the patch with the rest of polynucleotide chain.

Transcription-Coupled Repair

Transcription-repair coupling (TRC) allows cells to select some regions of the genome for NER in preference to others. In *E. coli*, as a consequence of a 436-fold induction of

β -galactosidase operon, 70% of the UV-induced pyrimidine dimers are removed from the transcribed strand of the induced operon within 5 min, whereas only 50% of dimers are removed from the nontranscribed strand after 20 min of repair. This selective removal of pyrimidine dimers from the transcribed strand of a gene is abolished in the absence of significant levels of transcription. The mechanism of TRC in *E. coli* is a complex one, and may include several subpathways. In one of them, TRC is achieved through the action of transcription-repair coupling factor (TRCF). TRCF is a product of mutation frequency decline (*mfd*⁺) gene, which maps at 25 min on the *E. coli* chromosome. The cloned *mfd*⁺ gene is translated into a 1148-amino-acid protein of ~130 kDa. The Mfd protein has consensus Walker type A nucleotide-binding motif, and, indeed, is a relatively weak ATPase. The Mfd protein can nonspecifically bind dsDNA (and less efficiently ssDNA) in an ATP binding-dependent manner, the ATP hydrolysis promoting its dissociation. The amino acid sequence of Mfd reveals motifs, which are characteristic of a number of DNA and RNA helicases. However, *in vitro* purified Mfd does not show either DNA or RNA helicase activity. The N-terminal 1–378 residues of Mfd, having a 140-amino-acid region of homology with UvrB, bind UvrA protein (Figure 7). The Mfd protein can also bind different

Figure 7 Crystal structure of Mfd. The Mfd structure (PDB ID 2EYQ): the domains that are homologous to UvrB homolog are shown in the same color scheme as for the UvrB molecule (1a in yellow, 2 in magenta, and 1b in green), and domain 2 is labeled as UvrA interacting domain. The translocation domain of Mfd, which is shown in orange, contains all seven SF2 helicase motifs which are shown in red. The RNAP interacting domain is shown in blue, and the TRG motif in light pink.

forms of *E. coli* RNA polymerase (RNAP). Amino acids 370–571 of Mfd are involved in this binding. *In vitro*, transcription inhibits NER of damage in a transcribed strand, whereas it has no effect on the coding strand. This inhibition is thought to result from RNAP stalled at the site of damage. Mfd is able to release stalled RNAP in an ATP-hydrolysis-dependent manner. Moreover, Mfd actually stimulates NER on the transcribed strand, so that it becomes faster than on the nontranscribed one. Based on all these observations, it is concluded that TRCF-Mfd carries out preferential repair of the transcribed strand by (1) releasing RNAP stalled at damaged site, and (2) recruiting the UvrA₂B₂ complex to damaged site through the high-affinity interaction with UvrA protein. The TRC in *E. coli* is influenced by the rate and conditions of growth as well as the level of gene transcription. In the LacZ gene, the Mfd-dependent mechanism of preferential repair dominates at basal levels of transcription, whereas Mfd-independent mechanisms prevail at induced transcription levels.

Conservation of NER from Bacteria to Humans

NER of bacterial, yeast, and mammalian cells have been reconstituted *in vitro* with purified proteins and defined damaged DNA substrates. Although it would appear that it takes nearly 25 proteins in a human cell to complete the process achieved by six bacterial proteins, there is a high degree of conservation of function from bacteria to eukaryotes. In fact, the recent structure of xeroderma pigmentosum group D indicates that it shares a common fold with UvrB and may have a similar mode of damage recognition. Thus, NER system of bacteria will certainly serve as a primary model for structure–function studies for years to come.

Glossary

Damaged DNA DNA in which the covalent structure, nucleotide sequence, or conformation has been altered.

DNA repair A collection of cellular processes whereby damaged DNA is restored to its normal chemistry, nucleotide sequence, conformation, and function.

Eukaryotes One of the kingdoms of life, more highly evolved than bacteria, the cells of which contain a defined nucleus.

Oligonucleotides Fragments of one or two DNA strands that can be of any size.

Transcriptionally active genes Genes that are in the active process of being transcribed into RNA.

The name nucleotide excision repair (NER) derives from the fact that during this process, damaged bases are excised from the genome as oligonucleotide fragments. This distinguishes NER from other types of excision repair such as base excision repair (BER), during which damaged bases are excised as free bases, and mismatch excision repair, during which mismatched nucleotides are removed from the genome as mononucleotides. The oligonucleotide fragments are generated by specific incision of the damaged DNA strand on either side of sites of base damage (bimodal incision) (Figure 1). The gaps (~30 nucleotides in length) generated by oligonucleotide excision are filled in by repair synthesis (Figure 1), using the intact opposite strand as an informational template. When the last nucleotide is inserted, the remaining nick is sealed by DNA ligase (Figure 1).

Modes of NER

NER transpires in cells in various subforms. Its operation on transcriptionally silent regions of the genome and on the nontranscribed strand of transcriptionally active genes is often referred to as global NER, to distinguish it from NER that specifically operates on the transcribed strand of transcriptionally active genes, so-called transcription-coupled NER (TC-NER). Additionally, both global NER and TC-NER are characterized by incision of the affected DNA strand on either side of sites of base damage (Figure 1); some lower eukaryotes support a form of NER that involves a single incision 5' to the site of base damage. This process is referred to as specialized NER.

The Biology of NER

Distribution in Nature

As we ascend the evolutionary ladder and encounter increasingly more complex organisms, our information about the cellular biology of NER becomes less precise, even though paradoxically our biochemical understanding has taken leaps and bounds in recent years. Several aspects of the cell biology of higher cells contribute to this paucity of information. Perhaps most importantly, both the structure and organization of the eukaryotic genome are much more complex than that of

prokaryotes. Eukaryotic genomes are considerably larger, and the requirements for packaging such large amounts of DNA into the limited confines of the cell nucleus have led to a complex structural organization. A consideration of the distribution of DNA damage in eukaryotes must take into account that nuclear DNA exists in intimate association with both histones and nonhistone chromosomal proteins, and that the structure of chromosomes reflects various levels of folding and coiling of the basic chromatin structural unit, the nucleosome.

Our present understanding of how chromosome structure and nucleosome conformation influence the enzymology of DNA incision and of postincision events during NER in eukaryotes is still scanty. It is certain that structural elements do, in fact, limit the access of repair enzymes to sites of base damage, and that specific perturbations of chromatin structure are necessary to facilitate NER.

Conventional NER involving the bimodal incision of damaged DNA is operationally and fundamentally similar in all organisms, from bacteria to humans. However, there are significant biochemical differences between NER in prokaryotes and eukaryotes. Additionally, the biochemistry of global NER and TC-NER differs in important details during the initial stage of the process. Specifically, during global NER, particular proteins are required for the recognition of base damage in DNA. In contrast, during TC-NER, the process of arrested RNA polymerase II transcription is believed to provide the mechanism of damage recognition.

The NER Machinery

NER operates through the assembly of a multiprotein complex. In bacteria, this complex comprises about six polypeptides. However, in both lower and higher eukaryotes, as many as 30 proteins are required for NER. These comprise proteins that participate in (1) the recognition of base damage, (2) bimodal incision of DNA, (3) oligonucleotide fragment incision, (4) repair synthesis of the gap generated in DNA, and (5) DNA ligation (Figure 1). In eukaryotes, the RNA polymerase II, basal transcription factor IIH (TFIIH), is an integral component of the NER machinery. As noted below, mutations in some of the genes encoding TFIIH subunits can result in disease states with transcription defects.

Figure 1 The general mechanism of nucleotide excision repair (NER) in eukaryotes. In the figure, yeast is used as an example. The red triangle represents some type of base damage that is recognized by the transcription-independent NER system. The binding of multiple proteins

Substrate Specificity

NER operates primarily on types of base damage that generate conformational distortion of the DNA helical structure. The so-called (6-4) photoproduct, a highly distortive type of base damage in DNA that results from exposure to ultraviolet (UV) light (Figure 2), as well as cyclobutane pyrimidine dimers (Figure 2), are premier examples of substrates for NER. The NER machinery does not recognize small loops or mismatches in DNA, and small chemical adducts such as those produced by methylation and the oxidation of bases are preferentially recognized by the BER process. The precise mechanism of substrate recognition during NER in eukaryotes remains to be determined.

Detection of NER *In Vivo* and *In Vitro*

Studies on NER in mammalian cells have historically utilized a variety of increasingly refined experimental strategies and techniques, many of which have been adapted from methods initially developed for studies with bacteria. Some of these procedures measure the damage-specific incision of DNA, either directly or indirectly. Others measure the physical excision of damaged nucleotides, repair synthesis of DNA, or the rejoining of strand breaks (DNA ligation). A particularly widely used technique for monitoring NER in living cells is referred to as the unscheduled DNA synthesis (UDS) assay, which identifies repair synthesis of DNA. In this procedure, cells in monolayer culture are exposed to a DNA-damaging agent such as UV radiation and the medium is supplemented with a radiolabeled precursor for DNA synthesis. Repair synthesis of DNA associated with NER is identified by a delicate autoradiographic stippling of nuclei in cells that are outside the S phase of the cell cycle (hence UDS) (Figure 3).

Kinetics of NER

Although the application of many of the experimental procedures mentioned above supports the existence of NER in higher organisms, the relative kinetics of specific events associated with NER, such as DNA incision, the excision of specific lesions from high-molecular-weight DNA, and repair synthesis in mammalian cells, are still controversial. In part, these controversies have arisen from the use of different experimental procedures, which, though designed to measure the same biological endpoints, sometimes have optimal reliabilities at different extents of DNA damage and under different

at or near the site of base damage in an ordered step-wise fashion generates a large multiprotein complex, the NE repairosome, which includes the RNA polymerase II basal transcription factor TFIIH. Two DNA helicase subunits in TFIIH (Rad3 and Ssl2 in yeast) facilitate the generation of a bubble in the DNA that is ~30 nucleotides in length and that flanks the site of base damage. The double-stranded/single-stranded DNA junctions are then recognized by two structure-specific endonucleases (Rad2 and Rad1/10). These cut the DNA duplex only on the damaged strand, generating an oligonucleotide fragment ~30 nucleotides in length. The Rad7/Rad16/Abf1 protein complex then facilitates displacement of the oligonucleotide as a free DNA fragment carrying the damaged base. Replicative DNA polymerases (δ and/or ε) together with accessory proteins (RPA, RFC, and PCNA) fill in the gap formed and DNA ligase seals the damaged DNA strand to restore complete covalent integrity.

Figure 2 Chemical structures of cyclobutane pyrimidine dimers (CPD) (a) and (6-4) photoproducts (b). Both of these photoproducts are generated in large amounts when DNA is exposed to UV light, including sunlight.

Figure 3 The identification of repair synthesis during NER in mammalian cells. The repair synthesis step shown in Figure 1 can be monitored in mammalian cells in monolayer culture. Mouse wild-type ($Xpc^{+/+}$) and NER-defective ($Xpc^{-/-}$) cells are exposed to UV radiation and allowed to incubate in the presence of [3H] thymidine. Cells in S phase of the cell cycle undergo intense autoradiographic labeling by incorporating the radiolabeled thymidine (black arrows). However, cells undergoing repair synthesis during NER incorporate much less label which can be identified as a delicate autoradiographic stippling (yellow arrow, $Xpc^{+/+}$). These grains are greatly reduced or absent in the NER-defective $Xpc^{-/-}$ cells.

experimental conditions, and hence may not be strictly comparable. Nonetheless, some of these apparent experimental inconsistencies may actually reflect real distinctions in NER associated with different cell types, different functional states of cells, particular regions of the genome, and different types of DNA damage. It is generally acknowledged that (6-4) photoproducts are removed from the genome of human, and from particular rodent cells, more rapidly than are pyrimidine dimers. It can take many hours before the latter lesions are fully cleared from the genome.

Defective NER and Human Disease

Several human hereditary diseases that result from defective NER have been identified. The so-called classical xeroderma pigmentosum (XP) is an autosomal-recessive disease that results from defects in both global NER and TC-NER. Affected individuals are extremely sensitive to sunlight and have a markedly increased risk of developing skin cancers. A clinically indistinguishable form of XP, called the XP variant form, derives from mutations that affect a different biological response to UV radiation-induced DNA damage. Individuals with mutations in genes required for both NER and RNA

polymerase II transcription can develop the clinical features of both XP and a different disease called Cockayne syndrome (CS). Pure CS (unaccompanied by XP) arises from defects in the CSA or CSB genes that encode proteins required for TC-NER. Unlike XP, CS does not lead to an increased risk of skin cancer in human subjects. Defects in subunits of TFIIH can result in a spectrum of diseases characterized by developmental and neurological defects with or without defective NER, the disease trichothiodystrophy being a notable example.

Mouse Models for Defective NER

Mouse models for each of the human hereditary diseases mentioned above have been generated by conventional targeted-gene replacement, and sometimes by more refined strategies. In general, these mice have proven to mimic the human disease well and have provided much valuable information about the relationships between defective NER and cancer predisposition and pathogenesis.

Glossary

Chromatin Compacted structure of DNA and proteins. DNA wraps around histones to form nucleosomes. A further compaction of the nucleosomes leads to various levels of condensation of the chromosomal DNA.

DNA helicase Enzyme that uses energy of adenosine triphosphate hydrolysis to separate the two strands of a DNA duplex molecule.

DNA ligase Enzyme that repairs single-stranded breaks in the DNA backbone by linking the 3' OH of the ribose to the 5' phosphate of the adjacent nucleotide.

Nuclease Enzyme that cleaves the bond between the ribose and the phosphate in the backbone of a DNA strand.

Photoproduct Cross-link between two adjacent pyrimidine bases in the DNA caused by ultraviolet irradiation. The two main photoproducts are cyclobutane pyrimidine dimers (CPDs) and 6–4 photoproducts.

Proliferating cell nuclear antigen (PCNA)

Clamp Multimeric protein forming a ring-like structure that is loaded on double-stranded DNA. It serves to anchor DNA polymerase on its substrate during DNA replication.

WD40 repeat Structural motif of about 40 amino acids often terminating in a Trp-Asp (W-D) dipeptide. WD40 repeat proteins contain 4–16 repeats that form a β -propeller structure.

Introduction

Genomic DNA is constantly threatened by endogenous and environmental factors causing damage to the bases or backbone of the DNA. If left unrepaired, such damage may block important processes such as DNA replication or transcription, leading to cell death. Alternatively, erroneous bypass of a lesion by the DNA polymerase may lead to mutations. To counteract the deleterious effects of DNA damage, a variety of DNA repair mechanisms have evolved. Among these repair mechanisms, nucleotide excision repair (NER) is unique in its capacity to repair a large variety of structurally unrelated lesions. It can remove cross-links induced by ultraviolet (UV) light, such as cyclobutane pyrimidine dimers (CPDs) and 6–4 photoproducts (6–4PP), and it also eliminates many types of bulky carcinogen–DNA adducts. The biological importance of NER is evident from the clinical features of patients with hereditary defects in this repair pathway, which include extreme sun sensitivity, elevated occurrence of skin cancer, neurological degeneration, and developmental delays.

Although eukaryotes and bacteria use a similar cascade of events to repair damaged DNA via the NER pathway, the proteins involved are not evolutionary related. Apparently, the two similar DNA repair systems have evolved independently in both kingdoms of life. The eukaryotic NER factors (listed in Table 1) have been characterized extensively both in human and in the budding yeast *Saccharomyces cerevisiae*, and the complete repair reaction has been reconstituted *in vitro* with the purified proteins (Figure 1).

Damage Recognition

For initial damage recognition during NER, two subpathways are used: transcription-coupled repair (TCR, discussed next) and global genome repair (GGR).

The GGR pathway is initiated by the XPC complex, which scans the DNA for aberrant structures. In this complex,

the 125-kDa XPC protein is associated with HHR23B, a 58-kDa homolog of the yeast Rad23 and the 18-kDa centrosomal factor centrin-2. The XPC protein is the actual damage-recognition subunit of the complex, whereas the two other subunits have a regulatory function by protecting XPC from degradation. XPC preferentially binds to DNA regions with impaired Watson–Crick base pairing, which can be indicative for presence of a damaged nucleotide. The co-crystal structure of the yeast homolog Rad 4 with DNA containing a damaged site revealed the mode of DNA binding (Figure 2). The main portion of the protein binds the double-stranded part of the DNA at the 3' side of the lesion. In addition, two β -hairpin domains of the protein fold into a hand-like structure that holds a small region of single-stranded DNA opposite the lesion. The Rad4 protein does not make any contact with the lesion itself, as can be expected for a protein that recognizes helix distortions caused by many different types of damage.

The level of active XPC in the nucleus is tightly regulated and responds at different levels to challenging conditions. Upon genotoxic stress, expression of XPC is enhanced at the transcriptional level; the protein is protected from degradation by interaction with HHR23B and centrin-2; DNA-binding activity of XPC is enhanced by posttranslational modification; and XPC is prevented from shuttling to the cytoplasm and accumulating in the nucleus.

As the main determinant for XPC binding is the presence of unpaired bases in the DNA, lesions that induce only a minor distortion are poorly recognized. An example of such a lesion is the UV-induced CPD. Efficient recognition of a CPD by XPC therefore requires an additional factor, UV-DDB. The UV-DDB complex, which consists of two proteins, DDB1 (127 kDa) and DDB2 (48 kDa), specifically binds to the two major UV photolesions CPD and 6–4PP. In contrast to XPC, UV-DDB does make contacts with the damaged bases by extruding them from the helix into a binding pocket of the DDB2 protein (Figure 2). The interaction of UV-DDB with the photoproduct subsequently facilitates the binding of XPC.

Transcription-coupled repair (TCR)		
CSA	-	
CSB	Rad26	

Yeast does not contain any homologs of the DDB proteins. Possibly, in this organism, other proteins can stimulate the binding of Rad4 to photoproducts, but such proteins have not yet been identified. However, yeast does contain another factor that is specifically required for the initial steps in GGR, a complex of the Rad7 and Rad16 proteins. The exact function of this complex is not yet known, but it has been proposed that it acts by remodeling the chromatin, thereby facilitating access of repair factors to damaged sites, which are obscured by nucleosomes.

Damage Verification and Formation of the Open Complex

Upon recognition of a mispaired DNA region by XPC, the next step in the repair reaction is to verify if indeed a lesion is present in this mispaired region. This is accomplished by the seven-protein TFIIH core complex. TFIIH was originally identified as a basal transcription factor required for RNA polymerase, to initiate transcription. The key components of TFIIH are the DNA helicases XPD and XPB. DNA helicases use the energy from adenosine triphosphate (ATP) hydrolysis for translocation along one of the strands of a DNA helix, thereby separating the two strands of the duplex. For transcription, this strand separation is required to generate a transcription bubble in which RNA polymerase can incorporate RNA nucleotides opposite one of the DNA strands. Moreover, in NER, the helicase activity of TFIIH also leads to a further opening of the DNA around the lesion creating a 10–20-bp bubble region. During translocation along the DNA strand, the helicases are arrested at a damaged site. In this way, TFIIH can not only confirm the presence of a lesion, but also discriminate which of

Figure 1 Two subpathways for eukaryotic nucleotide excision repair. In global genome repair (GGR), the damage is initially detected by the XPC complex. In transcription-coupled repair (TCR), RNA polymerase acts as a sensor for DNA damage. Both pathways are followed by a common cascade of events where the presence of the damage is verified by TFIIH, the DNA around the lesion is opened up by TFIIH, XPA, and RPA, and the DNA is incised by XPF-ERCC1 and XPG.

Figure 2 (a) Structure of the yeast Rad4 protein bound to DNA containing a photoproduct. Two β -hairpin domains bind to the DNA strand opposite the lesion. The photoproduct is flipped away from the protein. (b) Structure of the UV-DDB complex bound to DNA containing a photoproduct. The photoproduct is flipped into a pocket of the DDB2 subunit.

the two DNA strands is damaged. Mutational analysis has indicated that it is mainly the XPD helicase that serves as the damage-verification factor.

The formation of the open complex around the lesion is further stabilized by binding of RPA and XPA. RPA, consisting of three subunits, is a single-stranded DNA-binding factor that prevents reannealing of the separated DNA strands. The main function of the 31-kDa XPA protein is to coordinate the assembly of the different repair factors in the open complex. The XPA protein, however, was also shown to preferentially bind to sharply bent DNA structures. Therefore, this protein might serve as yet another damage-verification factor by probing the damage-induced bendability of the DNA.

Figure 3 Incision and DNA synthesis occur in a coordinated manner. XPF-ERCC1 induces the first incision on the 5' side of the lesion. The PCNA clamp is loaded on the DNA, and DNA polymerase extends the free 3' end. When DNA polymerase has proceeded halfway through the repair patch, XPG is triggered to incise the DNA at the 3' side of the lesion. Upon completion of the DNA repair patch, DNA ligase seals the remaining nick. For clarity, the other repair factors are omitted from the drawings.

Incision of the Open Complex

The creation of the open complex by the concerted action of the repair proteins discussed above leads to the formation of distinct junctions between double- and single-stranded DNA on both sides of the lesion. These junctions are specifically recognized by two structure-specific nucleases, XPG and the ERCC1-XPF complex. Depending on the actual size of the bubble in the open complex, XPG incises the DNA 2–8 nt from the 3' side and ERCC1-XPF 15–24 nt from the 5' side of the lesion. Interaction with repair proteins present in the open complex ensures that each nuclease will be positioned at the proper junction. Simultaneous action of both nucleases,

followed by simple release of the damage-containing oligonucleotide, would result in a large (24–32 nt) single-stranded gap. Such large gaps create a high risk in the cell for double-stranded DNA breaks and should be avoided.

Therefore, the processes of incision and resynthesis of DNA are tightly coordinated (Figure 3). The 5' incision by the XPF subunit of the ERCC1/XPF complex occurs first, creating a free 3'-OH group. The clamp loader RFC subsequently loads the proliferating cell nuclear antigen (PCNA) clamp near the junction, as is the case in DNA replication, after which polymerase δ initiates DNA synthesis from the free 3' end. Only after the DNA polymerase has proceeded halfway through the repair patch, the XPG protein is triggered to induce the 3' incision. This subsequently allows completion of the repair synthesis by polymerase δ after which the final nick is sealed by DNA ligase.

Transcription-Coupled Repair

In TCR, the RNA polymerase that moves along the DNA during RNA synthesis is used as the initial damage sensor. The elongating RNA polymerase is blocked when a lesion is present in the transcribed strand (Figure 1). Specific TCR factors recognize the stalled RNA polymerase, which subsequently leads to the recruitment of the core NER factors. Because the scanning of DNA by an elongating polymerase is much more efficient than by the association/dissociation of damage-specific proteins, the repair of the transcribed strand in any given gene is always faster than the repair of the nontranscribed strand.

Two proteins have been identified in humans, which are specifically involved in the coupling of repair to a stalled RNA polymerase, CSA, and CSB, but their precise functions are as yet unknown. The CSA protein (44 kDa) consists largely of multiple WD40 repeats, a feature commonly found in proteins that coordinate multiprotein complex assemblies. No

functional homologs of CSA have been identified in yeast. The CSB protein (168 kDa) and its functional yeast homolog Rad26 are related to the SWI/SNF family of ATP-dependent chromatin remodelers. This remodeling activity might serve to push the RNA polymerase back on its template (without dissociating it from its template), thereby allowing interaction of the repair factors with the damage site. The XPC protein is dispensable for TCR, most likely because the transcription bubble generated by RNA polymerase can be directly bound by the damage-verification factor(s) TFIIH and XPA. Strikingly, the XPC homolog from yeast, Rad4, is required both for GGR and for TCR. Apparently, in yeast, the transcription bubble does not allow direct binding of TFIIH and/or XPA.

Glossary

Chemosensation Any chemical sense, such as olfaction or taste. Very ancient, occurs in bacteria where it is used for chemotaxis.

Glomeruli Globular neuropil, which comprises synapses of olfactory receptor neurons.

Heptahelical A receptor with seven transmembrane helices, often, but not exclusively a G-protein-coupled receptor.

Odorant A chemically pure odor, that is, a single compound that activates an odorant receptor.

Olfactory code The neuronal representation of odors insofar as it is relevant to the encoding of these odors. Often confused with the neuronal representation, which is more commonly studied.

Pheromone An odorant that mediates intraspecies communication, eliciting neuroendocrine changes and stereotyped behavioral repertoires.

Olfactory receptors mediate the primary interaction of the olfactory brain with the external world. Any odor stimulus is initially represented as activation of one to many different olfactory receptors. Vice versa, anything that binds and activates an olfactory receptor is as per definition an odor, or odorant, as the single compounds are often called. Olfactory receptors constitute one of the largest families of G-protein-coupled receptors. Many large and small clusters of olfactory receptors are distributed throughout the genome. Olfactory receptors are expressed in a highly specific manner and monogenic expression is the general rule, that is, one neuron–one receptor. The molecular receptive range has been analyzed for several olfactory receptors. Generally, olfactory receptors have been found to exhibit a somewhat relaxed specificity toward ligands. However, some receptors, in particular, those for pheromones, show very high specificity. Olfactory receptors signal through specialized trimeric G proteins to open calcium-permeable nonspecific cation channels.

Olfactory Receptors Are G-Protein-Coupled Heptahelical Receptors

From a modest origin in simple eukaryotes such as yeast, G-protein-coupled heptahelical receptors (**Figure 1**) have evolved into the largest superfamily known. As the name indicates, signaling occurs through (trimeric) G proteins, with particular families making use of different G proteins. These receptors transmit biological effects of many hormones,

neurotransmitters, chemokines, and diverse sensory stimuli. Chemosensation constitutes an ancient function for this family. Already in yeast a dichotomy between sensing nutrients and sensing pheromones is found.

Whereas simple animals such as nematodes possess a single chemosensory sense, in higher animals several specialized systems have evolved, using olfactory and gustatory receptors, respectively. Olfactory receptors may recognize volatile or water-soluble odorants, depending on the species (e.g., mammals vs. fish), and the defining difference to taste receptors appears not to be the nature of the ligand, but the outreach of the system. Taste is generally considered to be a contact sense, whereas olfaction delivers long-range information.

Olfactory Receptors Segregate in Several Highly Divergent Groups

Thirteen years ago, the first higher eukaryote chemosensory receptors – mammalian odorant receptors (ORs) proper – have been identified. Linda Buck, then a postdoctoral fellow in Richard Axel's laboratory, used short motifs conserved in previously known heptahelical receptors to amplify a group of rat ORs from nasal complementary DNA via polymerase chain reaction. Like all heptahelicals, ORs exhibit the canonical seven-transmembrane domain structure (**Figure 1**) and the G-protein-interaction motif. Peculiar are the relatively short N and C termini. OR are a highly divergent group, and amino acid homologies below 20% have been reported within one

Figure 1 Schematic representation of an olfactory receptor. No crystallographical data are available for olfactory receptors. It is assumed that their structure is analogous to that of rhodopsin and the adrenergic receptor, which are more extensively studied. This is supported by some mutational analysis and molecular dynamics modeling. The scheme shown here is based on the structure of rhodopsin, whose crystal structure has been solved in 2000. Seven-transmembrane regions are depicted as cylinders. The binding site for ligands is centrally situated, between several transmembrane domains.

species. Between phyla, homologies have been so low as to be undetectable. Thus, in insect and nematode, chemosensory receptors have not been identified via homology searches, but by looking for orphan heptahelical receptors in either single-cell libraries or genomic databank searches.

Two classes of distantly related receptors have been found in the mid-1990s. They are designated V1R and V2R family, after their occurrence in the mammalian vomeronasal or accessory olfactory system. V1R receptors share the short N and C termini with the OR receptors, whereas the V2R exhibit a large extracellular N-terminal domain, and show some sequence homology to the Ca^{2+} -sensing receptor and the metabotropic glutamate receptor, a neurotransmitter receptor. In mice, the V2R family comprises ~100 genes and the V1R family contains ~150 genes, which segregate into 12 subfamilies designated V1Ra, V1Rb, etc. Humans and other hominoids have nearly no VR receptors as their accessory olfactory system is derelict and

their VR genes suffer ongoing pseudogenization. No intact human V2R is remaining and less than a handful of intact V1R genes have been identified in extensive genome searches.

It is commonly assumed but not rigorously shown that OR deal with common odors whereas VR are specialized for detecting pheromones – odors which are relevant in a social context as in kin recognition and mating.

It should be mentioned that there may be another, radically different group of olfactory receptors, a type of membrane-bound guanylate cyclases with a single transmembrane domain. Members of this family are expressed in specific subsets of olfactory receptor neurons. However, no ligands have been identified for them so far.

Gene Structure and Genomic Arrangement of Olfactory Receptors

Vertebrate OR and V1R feature an intronless coding region of ~1 kb that may be preceded by one to several noncoding introns. Alternative splicing is a frequent phenomenon for OR. Insect olfactory receptors and vertebrate V2R contain several introns within the coding region, as is common for other G-protein-coupled receptors.

The OR family size approaches 1300 identified genes in mouse, a species with a completely sequenced genome. About one-fifth are pseudogenes, a high percentage, which has people speculating about a putative role of the pseudogenes in the evolution of the gene family. The human OR gene family is of similar size; however, the percentage of pseudogenes is much higher, so that only ~350 OR appear functional in humans. Clusters of related genes are a frequent feature and indicate recent expansions of the respective gene lineages. Sometimes, other genes may be interspersed, a notable example being the intercalation of major histocompatibility complex (MHC) genes with OR reported for the mouse (but not for the human) genome. Overall, olfactory receptors are widely spread throughout the genome, asserting the ancient origin of this gene family.

Family sizes are smaller for lower vertebrates and insects – for *Drosophila* 60 receptor genes have been identified in the complete genome, mosquitoes possess ~80 olfactory receptor genes. For fish estimates range ~100 different OR. However, the occurrence of (smaller) clusters and the overall widespread distribution of receptor genes are equivalent to higher vertebrates. Surprisingly, the nematode *Caenorhabditis elegans* boasts ~1100 different chemosensory receptor genes (including 30% pseudogenes).

Monogenic and Monoallelic Expression of Olfactory Receptor Genes

Nematode chemosensory neurons, like taste receptor cells, express many different receptor genes per cell. Such bundling of receptors may be efficient if many different chemicals should lead to very few behavioral outcomes – mainly the choice between stay here and get out of here or swallow this and spit it out, respectively. As soon as a chemical sense is used for more sophisticated distinctions, it is imperative that more selective means of expression are used.

Figure 2 Olfactory receptors are part of the olfactory information processing pathway. (a) Olfactory receptors bind odorants and initiate a several-step signal-processing cascade. As endpoint, various channels are opened, leading to depolarization of the olfactory receptor neuron. (b) The olfactory receptors are mainly expressed on the cilia (or microvilli, not shown) of olfactory receptor neurons. These neurons generate action potentials in their axons and propagate them toward their terminals in the so-called glomeruli (glo). Glomeruli are neuropil structures and constitute the first relay station (synapse) in the olfactory-processing pathway. (c) Ciliated olfactory receptor neurons expressing the same odorant receptor are distributed within the sensory surface, but converge onto a common glomerulus. Microvillar receptor neurons such as those expressing the *V1R* and *V2R* genes converge onto several microglomeruli (not depicted here).

Accordingly, the expression of vertebrate and insect olfactory receptors is highly regulated. One particular olfactory receptor neuron expresses only a single type of OR gene or VR gene (Figure 2). This very restricted expression has been christened ‘monogenic expression’. In fact, for rodents it has been shown that expression is restricted even to one allele of a particular OR or VR gene, reminiscent of the monoallelic expression of immunoglobulin genes.

Some exceptions occur to the rule of one neuron–one gene. Notably a particular insect olfactory receptor, OR83b, has been found to be coexpressed in about two-thirds of all olfactory receptor neurons. This receptor is also highly unusual in that it is strongly conserved between many insect species. It is suspected that such atypical receptors may not have a role in odor detection, but serve another, so far unknown function.

Olfactory Receptor Gene Expression is Regulated by Proximal and Distal Control Regions

A stringent test for specificity of expression relies on the convergence of olfactory receptor neurons expressing the same receptor gene into a single glomerulus at a roughly fixed position (Figure 2). In several cases, such a restricted expression pattern could be reproduced faithfully by reporter gene

constructs containing variable segments of DNA flanking the coding region. It has been possible to narrow down control elements to regions of one to a few kilobases, but specific enhancer sites, transcription factors, or combinations thereof are just beginning to be identified. In some cases, all control elements appear to be situated close to the gene, whereas for others OR essential regulatory elements have been found in distances of ~100 kb from the coding region.

Selection of an OR gene for expression is a multilevel process. First, a choice is made for a particular subgroup of genes. Such subgroups feature spatially or temporally limited expression. In a second step, a particular OR is selected in a stochastic manner and then exerts negative feedback regulation onto all other ORs. Thus, monogenic expression of ORs is ensured.

Ligand Spectra Have Been Established for a Handful of Olfactory Receptors

Although hundreds of olfactory receptors have been cloned to date, ligands are only known for a small percentage of them. The difficulty of guessing potential ligands from among the enormous pool of potential odorants has been a major problem. Also, correct expression in heterologous systems has turned out to be unusually complicated, and has only been

Figure 3 Two types of olfactory processing: combinatorial vs. monospecific. To the left, the combinatorial representation of odorants is depicted. Different odors – here symbolized by various odor sources (skunk cabbage, skunk, rose, and lily) – activate overlapping, but distinctive combinations of olfactory receptors. This is also valid for the individual odor components, the odorants. Each odorant activates a particular subset of all olfactory receptors and thus each odorant generates a unique, if overlapping, fingerprint of olfactory receptor activation. To the right, monospecific representation of odorants is shown. A single compound activates a highly specific receptor very selectively, as is often observed for pheromones. Depicted here is a female silk moth, source of an attractive pheromone that is detected with extremely low threshold by the male of that species.

possible for some receptors. Most of the receptor molecules synthesized in heterologous systems are not transported to the plasma membrane, but remain in the endoplasmic reticulum, possibly because some unknown auxiliary molecules are missing. Indeed, for nematode chemosensory receptors, a chaperone has been shown to be essential for proper protein translocation, and V2R receptors are coexpressed with MHC class 1b molecules that appear to serve as escort molecules. For two OR genes, it has been possible to use a viral transfection method to express the recombinant OR in olfactory receptor neurons. In several cases, knockouts of particular olfactory receptors have served to identify receptor ligands, as first shown for the *C. elegans* ODR10 diacetyl receptor. The binding of ligands is not measured directly, but evaluated by a downstream parameter such as a change in membrane potential, or, more commonly, a rise in intracellular calcium levels.

Usually olfactory receptors respond best to a small group of highly related compounds and with lower sensitivity to further odorants. Often a particular functional group is preferred, but in some cases ligands with other functional groups may also activate the same receptor. Many strong ligands identified so far contain an aldehyde or keto group. The most extensive ligand analysis has been performed for the rat OR I7, which has *n*-octanal as the main ligand. Hydrocarbon chain length is another molecular feature that influences ligand efficacy. In the vast majority of cases, longer hydrocarbon chains result in more avid binding. From psychophysical experiments, it is known that also the shape and rigidity of the ligand molecule determine the olfactory sensation. Enantiomers of known ligands often, but not always, show differential responses. Taken together, a particular olfactory receptor requires a particular combination of molecular features in its cognate ligand/s.

Combinatorial versus Monospecific Representation of Odorants

Due to the monogenic expression of olfactory receptors, the ligand specificity of the olfactory receptor determines the odor

responses of the corresponding olfactory receptor neurons (Figure 2). Due to the convergence of olfactory neurons expressing the same receptor in single glomeruli (Figure 2), the ligand specificity of the olfactory receptor determines the odor responses in these glomeruli. This results in a rather direct map of the ligand specificities of the olfactory receptor repertoire on a two-dimensional surface in the corresponding brain region (the olfactory bulb in mammals, the antennal lobe in insects). Interestingly, mammalian OR influence the choice of a target glomerulus of olfactory receptor neurons as shown by gene-swap experiments. Insect olfactory receptors, on the other hand, appear not to be involved in selection of the proper target site.

Two complementary principles of odorant representation emerged from ligand binding studies *in situ* and in heterologous systems. First, many odorants activate a small subset of the large repertoire of ORs. Vice versa, any particular OR gets activated by a handful of different compounds, not just by a single compound. This results in a unique combination of activated receptors for each individual odor compound (Figure 3). The theoretical coding capacity of such a combinatorial representation is immense and much higher than needed – even for millions of different odors. In fact, the neuronal representation is sparse – the large majority of receptors do not respond to any given odorant – and thus suboptimal with respect to coding capacity. Nevertheless, humans (trained perfumers, that is) can distinguish and identify several thousand different odors, more than 10-fold the number of the functional human OR repertoire.

An alternative principle of neuronal representation seems to be realized for a smaller group of chemicals, including many pheromones. The high sensitivity and specificity of several such olfactory receptors (observed in mammals, fish, and insects) appears to indicate a monospecific interaction. A well-known example is the male/female attraction in silk moth, *Bombyx mori* (Figure 3). To integrate labeled line coding with hard-wired behavior appears straightforward. The coding capacity of such a system is low – it equals the number of different olfactory receptors devoted to this strategy – but sufficient for the limited

Figure 4 Signal transduction and termination of odor responses. A schematic representation of the main signaling pathway. AC, adenylate cyclase type III; ARR, β -arrestin-related molecules; G_{olf} , an α -subunit somewhat specific for the olfactory nervous system; GRK, G-protein-coupled receptor kinase; OR, odorant receptor. The cyclic nucleotide-gated channel is permeable for sodium and calcium, but gets blocked by calcium. GRKs phosphorylate the odorant receptor, which subsequently binds β -arrestin, leading to a complete stop of the signal transduction cascade.

number of potential pheromones. An example for a receptor/ligand pair is the mouse V1Rb2 receptor that specifically recognizes 2-heptanone.

Signal Transduction of Olfactory Receptors

All heptahelical olfactory receptors signal through trimeric G proteins. A controversy surrounding the signal transduction by OR has been more or less resolved. Vertebrate OR signal through G_{olf} , a specialized α -subunit, which in turn activates adenylate cyclase type III (Figure 4). The resulting cyclic adenosine monophosphate (cAMP) activates a cyclic nucleotide-gated channel that is a rather nonselective cation channel. Such channels are widespread in the nervous system, their particular gating properties are set by the subunit composition (A2A4B1b in the case of the mammalian olfactory channel). A considerable portion of inward current is carried by calcium (Figure 4). The resulting influx of calcium opens a calcium-gated chloride channel, resulting in chloride efflux, that is, in further depolarization and thus amplification of the signal (mammals, amphibians, and fish). Finally, the odor-induced signal is switched off by G-protein-coupled receptor kinase 3 (GRK3) and binding of arrestin-related molecules to the phosphorylated OR (Figure 4). Even with a constant odor stimulus the olfactory sensation is downregulated within seconds, in part, due to the peripheral mechanisms mentioned here.

The signal transduction cascade has not been worked out as well in invertebrates. Insects appear to also use cAMP as second messenger. Lobster may additionally employ IP₃ as a second signal transduction system that opens IP₃-gated channels situated in the plasma membrane. Such channels have been described in olfactory receptor neurons of many species, including fish and rodents, but appear to be a minor constituent compared to the number of cyclic nucleotide-gated channels. The effects described for IP₃ on olfactory signal

transduction in mammals and fish may reflect a modulatory role of this second messenger, conceivably in setting the basal activity level of olfactory receptor neurons. When all the evidence is weighed, a completely independent second signaling pathway for ORs appears not plausible.

Signal transduction for olfactory receptors of the VR type differs both from OR and between V1R and V2R. The emerging picture is that V1R signal via the G_{12} α -subunit and V2R via the G_o α -subunit. Finally, a transient receptor potential channel, TRP2, is activated by diacylglycerol and allows the influx of cations including calcium.

O-Linked GlcNAc Biosynthesis and Function

K Sakabe and G W Hart, Johns Hopkins University, Baltimore, MD, USA

Background

The post-translational modification of nuclear and cytoplasmic proteins on Ser and Thr residues by the addition of a single sugar moiety β -N-acetylglucosamine (O-GlcNAc) through an O-glycosidic linkage was originally described in 1984. The dogma at that time limited covalent modification of proteins by carbohydrates to occur solely in the extracellular space and within the ER, Golgi, and other subcellular organelles. Unlike the other types of glycosylation, O-GlcNAc is usually not elongated to more complex structures, making it a unique sugar modification. Since its discovery, O-GlcNAc has been found in some bacteria, some protozoa, and all metazoans.

The addition of O-GlcNAc to proteins, termed O-GlcNAcylation, is analogous to phosphorylation in its use as a signaling intermediate and regulatory mechanism. Indeed, global changes of O-GlcNAc occur during different stages of cell cycle, as well as upon mitogen stimulation. Like phosphorylation, O-GlcNAc is abundant and dynamically cycles on and off polypeptides. Because phosphorylation and O-GlcNAcylation can compete for the same or for adjacent Ser and Thr residues on a protein, these two post-translational modifications display a complex relationship: (1) phosphorylation and O-GlcNAcylation can compete for the same residue, which can determine protein function, and (2) the presence of O-GlcNAc or O-phosphate on one site can influence the occupancy of an adjacent site, the adjacent site being near either spatially in three-dimensional space or on the peptide sequence level. In addition, the enzymes that control O-GlcNAc cycling are regulated by phosphorylation, and some of the enzymes controlling phosphate cycling are regulated by O-GlcNAcylation.

O-GlcNAcylated proteins represent many different functional classes, indicative of the variety of roles that O-GlcNAc plays within the cell. Virtually, every cellular process is represented as follows: structural proteins such as keratins and intermediate filaments, signaling molecules including kinases and adaptor proteins, the translational machinery, the transcriptional machinery including coactivators and RNA polymerase II, the proteasomal degradation machinery, metabolic enzymes, chaperones, and nuclear pore proteins.

While many different kinases and phosphatases are found within the cell, there is only one set of O-GlcNAc cycling enzymes. UDP-GlcNAc:polypeptide transferase or O-GlcNAc transferase (OGT) catalyzes the transfer of the N-acetylglucosamine from uridine diphosphate N-acetylglucosamine (UDP-GlcNAc) to the hydroxyl group of specific Thr and Ser residues. β -D-N-acetylglucosaminidase or O-GlcNAcase, on the other hand, hydrolyzes the sugar moiety from the protein. Despite having only a single catalytic subunit, both of these enzymes are specifically targeted to their substrates by forming transient interactions with many other proteins to form a functional holoenzyme complex.

Biosynthesis of UDP-GlcNAc

The activated sugar donor, UDP-GlcNAc, is an example of a molecule exquisitely controlled by different pathways of cellular metabolism, including nucleotide, glucose, amino acid, and fatty acid metabolism. In addition, the formation of UDP-GlcNAc is sensitive to the overall energy status of the cell. The relative levels of each component determine the availability of UDP-GlcNAc for modifying different proteins, making this sugar donor an important sensor of overall nutrient status for the cell.

UDP-GlcNAc is synthesized via the hexosamine biosynthetic pathway. Approximately 2–5% of the glucose taken up by the cell is shunted through this pathway to generate amino sugars and activated amino sugars. The rate-limiting enzyme of the hexosamine biosynthetic pathway glutamine-fructose-6-phosphate-transaminase, or GFAT, controls how much glucose is diverted into sugar nucleotide synthesis (Figure 1).

O-GlcNAc Transferase

OGT is evolutionarily conserved from *Caenorhabditis elegans* to *Homo sapiens*, showing greater than 60% amino acid identity and 80% amino acid similarity between species. In fact, amino acid identity is around 99% when comparing sequences from higher-order species such as human, mouse, and rat. This degree of sequence conservation between species suggests an evolutionary constraint in maintaining primary sequence and tertiary structure. Further highlighting the importance of this enzyme, ablating this gene is lethal for mice, fruit flies, and plants, demonstrating the essential nature of this post-translational modification.

Although the predominant form of OGT is an enzyme of 110 kDa (ncOGT), two other isoforms of OGT have been identified, arising from different splice variants: a 103 kDa isoform targeted to the mitochondria (mOGT) and a 78 kDa short form of OGT (sOGT; Figure 2). While the C-terminal catalytic portion of the enzyme is identical between isoforms, they differ in the N-terminal tetratricopeptide repeat (TPR) domain. TPRs are structural motifs comprised of 34 amino acids that mediate protein–protein interactions or multimeric complex formation. TPRs are typically found in tandem repeats. OGT is no different in that the number of repeats ranges from 2, in the short isoform, to 13, for the full-length protein. mOGT also contains a mitochondrial localization sequence. In addition, OGT contains a binding domain for phosphatidylinositol 3,4,5-triphosphate (PIP3), a signal intermediate generated upon activation of growth factor receptors, allowing OGT to associate with the phospholipid bilayer of the plasma membrane in a signal-dependent manner.

No consensus sequence is known for OGT; however, a Pro residue within one to three amino acids of the modification

Figure 1 The hexosamine biosynthetic pathway. The diagram depicts how glucose is metabolized into UDP-GlcNAc.

site occurs frequently. Recent structural analyses have also provided insight into how the two domains of OGT function to O-GlcNAcylate substrates. A composite structure of the TPR domain of human OGT with a bacterial ortholog of OGT, *Xanthomanas campestris* OGT (XcOGT), reveals a corkscrew-like structure with the TPRs forming an extended superhelix and the catalytic portion adopting a typical nucleotide sugar-dependent glycosyltransferase fold. The inner portion of the TPR superhelix is lined with Asn residues, forming potential sites for interacting proteins. Interestingly, the TPR proximal to the catalytic domain faces the active site, thereby creating a surface by which substrates can interact. This conformation leaves the remainder of the TPR domain available for protein binding. Sequential deletion of the TPRs reduces the ability of OGT to O-GlcNAcylate protein substrates while retaining its ability to modify short peptide substrates. These observations suggest that OGT interacts with its substrate through its TPR domain and that the TPRs form a platform that can recruit target molecules to OGT. Moreover, the majority of different targeting proteins, or proteins that direct OGT to O-GlcNAcylate substrates specifically in a signal-dependent manner, interact with OGT through the TPR domain. This model explains how OGT is able to O-GlcNAcylate many different types of proteins and, in fact, this model is reiterated throughout nature as phosphatases use targeting subunits to direct them to specific substrates.

O-GlcNAcase

The enzyme that catalyzes the hydrolysis of the O-GlcNAc moiety, O-GlcNAcase, is a monomeric enzyme of 916 amino acids. The N-terminus contains the catalytic activity with a putative acyltransferase domain on its C-terminus. A shorter isoform resulting from an alternative splicing site yields a truncated enzyme lacking approximately 230 amino acids from its C-terminus and is identical to the full length enzyme except for the last 15 amino acids (Figure 3). Both forms are expressed ubiquitously.

Purification of O-GlcNAcase from cow brain shows that O-GlcNAcase is found within a high-molecular-weight complex suggesting an association with other proteins for regulation and specificity. In *in vitro* O-GlcNAcase assays, O-GlcNAcase can cleave GlcNAc from glycopeptides and from the chemical substrate paranitrophenyl-GlcNAc, but not efficiently from proteins, indicating that auxiliary factors are also required by O-GlcNAcase for substrate recognition.

In addition, O-GlcNAcase is a substrate for proteolytic cleavage by one of the executioner caspases, that is, Caspase-3. Upon initiation of apoptosis, O-GlcNAcase is cleaved between the catalytic domain and its C-terminus. These two halves remain associated and retain activity, so it is still unclear why O-GlcNAcase is cleaved during apoptosis.

Figure 2 The structure of OGT. The upper portion depicts the domain architecture of the three OGT isoforms. The lower portion is a composite image for the TPR domain of human OGT overlaid (PDB:1W3B) with the bacterial ortholog XcOGT in complex with UDP-GlcNAc phosphonate analog in red (PDB:2JLB). The dark blue indicates the location of the PIP3-binding domain. The vast alignment algorithm was used to align the human OGT and XcOGT. MacPymol was used to create structural images.

Function and Physiological Importance

Modification with O-GlcNAc leads to a variety of outcomes for the protein, including regulation of enzyme activity, protein–protein interaction, and altered degradation. A variety of functions will be discussed below in different cellular contexts.

One of the largest classes of proteins modified with O-GlcNAc are components of the transcriptional machinery, such as transcription factors, chromatin remodeling enzymes, as well as RNA polymerase II itself. O-GlcNAcylation can affect the ability of certain transcription factors to interact with the transcriptional machinery, such as STAT5A, which requires O-GlcNAcylation for interaction, or cAMP response element-binding protein (CREB), where O-GlcNAcylation decreases affinity to basal transcription factors. In addition, it can affect the ability of a transcription factor to bind its cognate sequence, as in the case of PDX-1, where O-GlcNAcylation enhances its DNA-binding affinity. O-GlcNAc can also regulate chromatin architecture by modifying chromatin remodeling enzymes. For example, O-GlcNAcylation of MLL5 activates its histone lysine methyltransferase activity, which in turn activates transcription from certain promoters. Finally, O-GlcNAcylation can affect the subcellular location of some transcription factors. By determining nuclear or cytoplasmic localization, O-GlcNAc can enhance or repress transcription, respectively.

O-GlcNAc also plays a role in regulating protein degradation. For example, O-GlcNAcylation can protect proteins from degradation, such as for the transcription factors like the

estrogen receptor, the oncogene c-myc, and the tumor suppressor p53. Many proteins of the proteasome are O-GlcNAcylated, and increasing O-GlcNAc levels on the proteasome inhibits its adenosine triphosphatase (ATPase) activity, thereby reducing proteasome-mediated degradation.

The ability of the cell to tolerate various insults is mediated by the stress response pathway. Global O-GlcNAc levels increase during stress, and preventing this increase decreases cell viability. The protective effect of O-GlcNAc during stress is partly through the upregulation of heat shock proteins.

Misregulation of O-GlcNAc occurs in numerous disease pathologies such as type II diabetes, Alzheimer's disease, and cancer. Hyperglycemia and insulin resistance are hallmarks of type II diabetes. Since generation of UDP-GlcNAc is sensitive to the amount of glucose and glucosamine available, hyperglycemic conditions are believed to increase UDP-GlcNAc levels within the cell and thus increase the amount of O-GlcNAcylated proteins. Increasing O-GlcNAc levels genetically or pharmacologically causes insulin resistance; therefore, OGT appears to play a key role in the pathology of type II diabetes.

A major component of neurofibrillary tangles associated with Alzheimer's disease is the microtubule-associated protein tau. In the diseased state, tau becomes hyperphosphorylated. Under normal conditions, tau is modified with O-GlcNAc; it is hypothesized that by decreasing the amount of this modification on tau, perhaps due to defective glucose metabolism in the neuron, tau becomes hyperphosphorylated and forms the aggregates associated with Alzheimer's disease.

Figure 3 The structure of *O*-GlcNAcase. The upper portion shows the domain architecture of *O*-GlcNAcase. NAGdase domain contains the hexosaminidase activity. The orange domain is the putative acetyltransferase activity domain. The sO-GlcNAcase contains a unique 15-amino-acid sequence on its C-terminus, which is indicated in black. The lower portion of the figure shows the crystal structure of one of the bacterial orthologs for *O*-GlcNAcase in complex with the inhibitor Nag-thiazoline in red (PDB:2J4G). The ortholog contains only the hexosaminidase domain. The left-hand portion is looking down the catalytic domain while the right-hand portion is a 90° rotation on the *x*-axis. MacPymol was used to generate structural images.

Finally, a decrease in *O*-GlcNAc has been seen in cancerous tissue. In fact, increased *O*-GlcNAcase activity and decreased *O*-GlcNAc levels correlated with tumor grade. In addition, Thr 58 of *c*-Myc, an oncoprotein, is the major *O*-GlcNAc site on this oncogene protein and is also a mutational hot spot in Burkitt's lymphoma. In quiescent cells, *c*-Myc is mainly *O*-GlcNAcylated at Thr 58, but this site becomes rapidly phosphorylated upon growth stimulation.

In summary, *O*-GlcNAc is an abundant and dynamic post-translational modification in many organisms, including all metazoans and viruses that infect them. It has a complex interplay with phosphorylation and in turn plays a key role in regulating cell signaling, transcription, and cytoskeletal functions.

Opioid Receptors

P Y Law and H H Loh, University of Minnesota, Minneapolis, MN, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

G-protein-coupled receptors (GPCRs) Membrane receptors that transduce their signals via the heterotrimeric G proteins consisting of α - and $\beta\gamma$ -subunits. Activation of these receptors results in the dissociation of GDP from and association of GTP to the α -subunit. The association of GTP causes the dissociation of the heterotrimeric protein into the α - and $\beta\gamma$ -subunits leading to subsequent effectors' activation or inactivation. The enzyme GTPase within the α -subunit will hydrolyze the GTP to GDP resulting in the reassociation of the α - and $\beta\gamma$ -subunits, thus terminating the signaling of the receptor.

Intronic sequences Sequences within the gene that are removed by RNA splicing to generate the final mature RNA products of a gene that could include those that generate proteins, ribosomal RNA, or transfer RNA.

Mixed agonist–antagonists Opioid ligands that could have full agonist activity in one opioid receptor type but also act

as antagonist in another opioid receptor type. Therefore, their pharmacological profiles resemble the activation of one receptor type and inactivation of another receptor type.

Regulator of G-protein signaling (RGS) Multifunctional, GTPase activating protein or protein structural domains that promote GTP hydrolysis by the α -subunit of the heterotrimeric G proteins, thereby accelerating the termination of the GPCR signaling.

β -Arrestins Cellular proteins involved in the dampening of the cellular responses as a result of agonist-induced activation of the GPCR. Agonist-induced activation of GPCR leads to phosphorylation of the receptor and facilitating the β -arrestin binding. The bound β -arrestin could attenuate the G-protein interaction with the receptor, thus preventing the signal transduction. But the bound β -arrestin could also serve as scaffold for other cellular proteins, such as MAP kinase or clathrin, thus resulting in the transduction of alternative signals and the endocytosis of the receptor.

Opioid receptors are transmembrane proteins located at the synaptic membranes that serve as targets of an efficacious pain relief drug: morphine. The identification of these binding sites at neural membrane for plant alkaloids has led to the discovery of the first class of endogenous drug molecules, that is, the enkephalins and endorphins. These opioid receptors belong to the superfamily of G-protein-coupled receptor (GPCR), and upon activation, the activities of multiple cellular effectors are modulated, leading to inactivation of the ascending and activation of the descending pain pathways. Eventually, pain perception is altered. Unfortunately, with the good therapeutic actions of morphine, there are also bad side effects of the drug, for example, tolerance and addiction. Thus, the molecular mechanism in the cellular regulation of these opioid receptors, and the designs of specific agonists for these opioid receptors to be ideal analgesic agents are of great interest in pain medicine development.

Historical Perspectives

For centuries, extracts from the opium poppy, *Papaver somniferum*, have been prescribed for pain relief, to control cough, and to treat diarrhea. However, in addition to its medicinal uses, due to its psychological effects, man has abused opium since the time of the ancient Greeks. The isolation of the principal alkaloid by the German pharmacist, Friedrich W Serturner in 1805, which he named morphine after the Greek god of dreams, Morpheus, has enabled pharmacologists to determine the relationships between structures and their analgesic activities. From the relatively low concentration of morphine needed to relieve pain in 70% of the patients (10 mg

70 kg⁻¹ body weight) to the stereoselective requirement for analgesic action of the drug, it is apparent that morphine acts by high affinity binding to proteins, or specific receptor, located in the central nervous system (CNS). The presence of a specific morphine receptor was not demonstrated until 1973, when three research groups – Lars Terenius, Solomon Snyder, and Eric Simon, following the guideline established by Avram Goldstein – independently reported the presence of high affinity and stereoselective binding sites at the synaptic membrane preparations of rodent brain. The affinities of various opiate analgesics for these binding sites and the location of these sites correlated well respectively with the *in vivo* potencies and sites of action of the drug. Thus, the era of the opiate receptor is launched. Immediately, it is apparent that these mammalian CNS binding sites could not be evolved for plant alkaloids. This dichotomy was resolved by the isolation of the endogenous opioid peptide, enkephalin, by John Hughes and Han Kosterlitz in 1975 followed later by the identification of the proenkephalin A gene. The subsequent identification of two other gene products, β -endorphin deriving from the pro-opiomelanocortin gene and dynorphin deriving from the *prodynorphin* or *proenkephalin B* gene, suggests that the *in vivo* actions of morphine and its congeners must be a reflection of these endogenous opioid peptides actions. The presence of multiple endogenous opioid peptides genes also suggests the probable existence of multiple opioid receptors.

Discovery of Multiple Opioid Receptors

In 1976, Bill Martin and his colleagues hypothesized the presence of multiple opioid receptors. Concluding from the

physiological responses such as blood pressure and respiration, Martin and co-workers coined the multiple opioid receptors terminology based on the prototypic ligands within each group, with morphine being the mu (μ) agonist, ketocyclazocine being the kappa (κ) agonist, and SKF10 047 being the sigma (σ) agonist. The existence of multiple opioid receptors was further demonstrated by measuring the amount of an opiate antagonist to reverse the agonist effect in two *in vitro* bioassay systems, the guinea pig (GP) ileum and the mouse vas deferens. These bioassays were responsible for the identification of the fourth type of opioid receptor, the delta (δ) with enkephalin being the prototypic agonist. Additional studies such as the cross-tolerance measurements also supported the existence of multiple opioid receptors. In the cross-tolerance studies, animals or the *in vitro* GP ileum were treated with an opioid receptor-selective agonist. Chronic exposure to the agonist resulted in a loss in response, or tolerance development. However, activities of agonists that are selective for other opioid receptors remained unaltered, or no cross-tolerance was developed. These *in vivo* and *in vitro* experiments support the original hypothesis of multiple opioid receptors.

The implication of the existence of multiple opioid receptors by the animals' studies and bioassays was supported initially by the direct receptor-binding experiments reported by Law and Loh, KJ Chang, Hans Kosterlitz, and their colleagues. The development of receptor-selective antagonists, such as naltrindole (δ) and nor-binaltorphimine (κ), and the development of ligands that would alkylate receptor selectively, such as β -funaltrexamine (μ), have enabled investigators to characterize the properties of these multiple opioid receptors biochemically further by generating membrane preparations that contain single-receptor type. Only after the molecular cloning of the δ -opioid receptor, concurrently by the groups of Chris Evans and Brigitte Kieffer in 1992, followed by the cloning of μ - and κ -opioid receptors in 1993 by others, is the hypothesis of multiple opioid receptors firmly established. These multiple opioid receptors are products of three separate receptor genes and with high amino acid sequence homology (>60%). Although subtypes of these opioid receptors have been postulated, various gene products that exhibit the reported ligand selectivity of the various opioid receptor subtypes have not been identified. Also, from additional pharmacological and the molecular cloning studies, the sigma (σ) receptor does not belong to the opioid receptor family. Hence, the μ -, κ -, and δ -opioid receptors are the sites where endogenous opioid peptides and exogenous opiate alkaloids exert their actions.

Distribution and Pharmacology of Multiple Opioid Receptors

Prior to the cloning of the opioid receptors, the distribution of the receptors within various brain regions or tissues was determined with autoradiographic studies using radioactive ligands selective for a specific receptor. These autoradiographic results were later substantiated and extended with the *in situ* hybridization studies using the cloned receptor messenger RNA (mRNA) and with the histochemical or immunofluorescence studies using the receptor-specific antibodies. In general, these data indicate that the location of the multiple opioid receptors

coincides with the pharmacological actions of the drugs. These opioid receptors are mainly localized in the limbic system that are involved in the control of emotion and reward behaviors, the ascending and descending pain pathways that include the different laminae layers of cortex, thalamus, periaqueductal gray, midbrain median raphe and the dorsal horn of the spinal cord, and specific brain regions that are known to control locomotion, emesis, cough, and temperature.

The distributions of the μ - and δ -opioid receptor are very similar but distinct. Although these receptors do not colocalize in the pre- or post-synaptic membrane of the same neuron, they are observed to be located in the same components of the limbic systems such as the nucleus accumbens and the amygdala. Their locations at the cortex, the 4th ventricle and at the substantia gelatinosa of the spinal cord are the reasons why both μ - and δ -opioid receptor-selective drugs have strong spinal and supraspinal analgesic effects. Similarities in the distribution of these two opioid receptors suggest that the μ - and δ -opioid receptors have a similar pharmacological profile (Table 1). There are reports using δ -opioid receptor-selective antagonist or using mice that the δ -opioid receptor has been genetically deleted that implicate the role of δ -opioid receptor in modulating both the acute and chronic effects of the μ -opioid receptor selective agonist.

On the other hand, distribution of the κ -opioid receptor in the CNS is distinct from that of μ - and δ -opioid receptors. The most striking difference is the uniform pre-synaptic location of the κ -opioid receptor in the caudate putamen area. Such location could be the explanation for the observed κ -opioid-agonist-induced decrease in locomotion and the decrease of dopamine release in this brain area. The inhibition of dopamine release is the basis for the dysphoric effects of the κ -opioid agonists. The brainstem and spinal cord distribution of the κ -opioid receptor resemble that of μ -opioid receptor. Hence, κ -opioid agonists could produce spinal analgesia (Table 1).

The identification of these three types of opioid receptor could not account for the various receptor subtypes reported by the pharmacological studies. Such discrepancy could stem from the nonselective nature of the ligands for the receptors, or that there might be multiple receptor molecules generated from the three opioid receptor genes. The coding sequences of opioid receptors are not continuous within their respective genes. There are gaps, or intronic sequences, within the receptor genes. Thus, it is possible during the maturation of the

Table 1 Pharmacological effects associated with the multiple opioid receptor

messenger RNA (mRNA), different portions of the gene are spliced together, splice variants, resulting in different receptor protein structures and pharmacological properties. It is also possible that these three opioid receptors could form oligomers. The hetero-oligomers, that is, oligomers formed with different opioid receptors, will definitely exhibit different pharmacological properties from the homo-oligomers, that is, oligomers formed with same opioid receptor, and from the monomer. Opioid receptor existing in oligomeric forms have been implicated in numerous studies in cell model studies. Whether the three opioid receptors do exist in oligomeric forms at the synapse remains one of the questions to be addressed.

The multiple opioid receptors are not confined to the CNS. The presence of the receptors in the gastrointestinal tract accounts for the constipative effect of μ - and δ -opioid agonists. The presence of the κ -opioid receptor in the cardiac myocytes could be the reason for the bradycardia effect observed with the κ -opioid agonists, though the bradycardia effect of the opioid agonists is mainly associated with the agonist actions at the brainstem medulla. Opioid receptors have been reported also to be present in the immune cells. The true identities of these receptors are yet to be identified, whether they are the μ -, δ -, or κ -opioid receptor types or the nonclassical opioid receptors. Nevertheless, the pronounced effects that morphine has in the immune responses of animals, and the fact that intravenous drug users are one of the high-risk groups for HIV have led to many studies, and the effects of various opioid agonists and antagonists on the functions of immune cells cannot be ignored.

Opioid Ligands Selectivity for the Multiple Opioid Receptors

With the cloning of the opioid receptors and the subsequent generation of mice in which the transcription of selective opioid receptor gene could be disrupted, it is possible now to delineate the opioid receptor types that various opioid ligands could activate. By expressing the three cloned receptors individually into cells that do not express opioid receptor endogenously, it is possible to generate models that could determine the affinities of the opioid ligands to a specific receptor type accurately. Likewise, by genetically eliminating the *in vivo* expression of an individual opioid receptor type, the loss or gain in functions of a specific opioid agonist can be evaluated *in vivo*. These data in combination with the receptor-selective antagonists studies have determined the selectivity of various opioid ligands and their functions, as summarized in Table 2.

It is apparent that morphine and its congeners are agonists in the μ -opioid receptor. Although in the *in vitro* cell line, models that express the δ -opioid receptor morphine has partial agonist activities, morphine does not exhibit measurable analgesic activities in mice that do not express the μ -opioid receptor. Since these animals have intact δ - and κ -opioid receptor systems, it is unequivocal that morphine pharmacological effects are mediated via the activation of μ -opioid receptor.

Other opiate alkaloids have been shown to exhibit nonselectivity toward these three opioid receptors. The oripavine derivatives (etorphine and diprenorphine) and the benzomorphans (ketocyclazocine and bremazocine) have been shown

Table 2 Relative receptor selectivity of various opioid ligands and their functions in respective receptors

AG, agonist; PA, partial agonist; AN, antagonist.

by many to have similar affinities for all three opioid receptors. This is surprising since ketocyclazocine was used by Bill Martin to define one of the multiple opioid receptors, the κ -opioid receptor. Such dichotomy may be resolved by the fact that some opiate alkaloids have different activities in different opioid receptor types. For example, nalorphine exhibits antagonistic properties in the μ - and δ -opioid receptors but possesses agonistic activities in the κ -opioid receptor. Another example is pentazocine that possesses both κ -agonistic and μ -antagonistic properties. The mixed agonist–antagonist properties of various alkaloids are being exploited in the clinic so as to minimize the side effects of the drug, most noticeably, the addictive liability of the opiate analgesics.

The endogenous ligands, noticeably the products of the three peptides genes – enkephalin, β -endorphin, and dynorphin do not appear to have specificity toward these multiple opioid receptors. Initially, enkephalin and β -endorphin have been considered to be the prototypic ligands for the δ - and μ -opioid receptors, respectively. Dynorphin, with the positively charged amino acids, arginine and lysine, has been shown to preferentially interact with the κ -opioid receptor. Since then, it has been shown that Met⁵-enkephalin has equal affinity for the μ - and δ -opioid receptor, and that dynorphin has high affinity for the δ -opioid receptor. Only when the peptides are restricted in their rotation is receptor selectivity observed, for example, the D-penicillamine derivatives of enkephalin, DPDPE. This peptide has been shown *in vitro* to be selective for the δ -opioid receptor and with minimal activity in the μ -opioid receptor. Hence, the *in vivo* effect of DPDPE has been the hallmark for the δ -opioid receptor activation. However, recent *in vivo* studies using mice lacking the μ - or the δ -opioid receptor, clearly suggest that the DPDPE analgesic effect is mediated by activation of

μ -opioid receptor. This conflicting *in vitro* and *in vivo* receptor selectivity of the endogenous peptides and their derivatives requires further detailed investigation.

Molecular Mechanism of Multiple Opioid Receptor Function

A general feature of the opioid agonist is the inhibition of neurotransmitter release. Although there are instances that opioid agonist could increase the neurotransmitter release, it is due to the location of the receptor and the disinhibition of the neurotransmitter release. An excellent example is the dopamine release within the nigrostriatal loop. κ -Opioid agonist inhibits dopamine release by acting directly at the presynaptic dopaminergic terminals, whereas μ - and δ -opioid agonists increase the release by inhibiting the GABAergic interneurons that inhibit the dopamine release. Thus, in either case, the activation of opioid receptor results in the direct inhibition of synaptic transmission.

From the cloning studies, it is unequivocal that the opioid receptors belong to the superfamily of proteins, the GPCRs and the subfamily of rhodopsin-like receptors. One common feature of these receptors is that they contain hydrophobic regions that would span the membrane 7 times. Thus, these receptors are commonly known as 'seven-transmembrane receptors'. Another common feature is that their signals are mediated by promoting the dissociation of the nucleotide guanosine diphosphate (GDP) from the α -subunits of the heterotrimeric proteins. The dissociation of GDP allows the association of guanosine triphosphate (GTP) to the α -subunits resulting in the dissociation of the heterotrimeric proteins into α - and $\beta\gamma$ -subunits. These subunits will then control the activities of various intracellular or membrane-bound proteins and enzymes. For the multiple opioid receptors, the GTP/GDP-binding proteins involved in their actions are the pertussis-toxin-sensitive Gi/Go proteins.

In order for opioid receptors to regulate the neurotransmitter release, two of the proteins that the receptors regulate are the voltage-dependent Ca^{2+} channels and the inward rectifying K^{+} channels. By inhibiting the Ca^{2+} channels and thus reducing the influx of Ca^{2+} , opioid agonists could regulate the fusion of vesicles containing the neurotransmitters with the synaptic membrane. Also opioid agonists could activate the voltage-dependent inward rectifying K^{+} channels and thus hyperpolarizing the synaptic membrane. By controlling these two ions channels, activation of the opioid receptors would reduce the excitability of the membrane and reduce the transmitter release.

Other prominent proteins and enzymes that are regulated by the multiple opioid receptors are the enzymes responsible for cyclic adenosine monophosphate (cAMP) synthesis, adenylyl cyclase, and that which is involved in the long-term cellular adaptational events, the mitogen-activated protein kinase (MAP kinase). Opioid receptors inhibit the adenylyl cyclase activity, thereby reducing the intracellular cAMP content. This second messenger could control the activities of a protein kinase that, in turn, could regulate the activities of other proteins, such as the ion channels. The MAP kinase has been known to participate in the cellular proliferation and

apoptotic events. Thus, it is probable that MAP kinase activation by the multiple opioid receptors could signify their involvement in long-termed potential and learning, two of the probable mechanisms for the basis of chronic drug actions.

The complexity of opioid receptor signaling lies not only in the integration of all the signals from these effectors activated by the receptor, but also in the signal duration, intensity, and the pathway selected in signaling. There are accumulative evidences in support of the aggregation of cellular proteins or scaffolding of signaling molecules upon agonist activation of the receptor. Some of these molecules are protein kinases that could phosphorylate the receptor or G proteins leading to blunting of the signals. There are proteins such as regulator of G-protein signaling (RGS) that affect the GTP hydrolysis thereby altering the duration and magnitude of the G protein activity. Opioid receptor could interact also with the cellular protein β -arrestin, which in addition to terminating the original receptor signals, could initiate new signals due to its ability to serve as scaffold for other cellular proteins. Thus, depending on the conformation of the agonist-receptor complex, and the ability to recruit various cellular proteins to the receptor complex, different opioid agonists have shown to exhibit agonist-dependent pathway-selective signaling, or biased agonism. This is best demonstrated in the receptor-mediated activation of MAP kinase, in which morphine and fentanyl, two agonists used extensively in the clinics, required either G protein or β -arrestin to activate the kinase. The consequence of such pathway-selective activation of MAP kinase is manifested in the different genes being regulated by the two opiate agonists. Such difference has implications in the chronic usage of the drugs.

Summary and Future Direction

The similarities in the sequence and the molecular action of these multiple opioid receptors are striking. Hence, it is unclear why nature would evolve three different genes coding for three different proteins from the same ancestral gene so as to carry out the same functions. To complicate the picture, there are three endogenous peptides that exhibit selectivity but not specificity among these multiple opioid receptors. It is still unresolved why an endogenous opioid peptide such as Met⁵-enkephalin that exhibits *in vitro* agonistic properties in μ -opioid receptor would not produce analgesic effect *in vivo*. The physiological function of the endogenous ligands remains elusive also. There is no debate that endogenous peptides and opiate alkaloids have different recognition motifs within these opioid receptors, and that the cellular regulations of the peptide- and alkaloid-receptor complexes are different. Whether such differences could contribute to the differences in the pharmacological responses of these drugs or simply the spatial distribution of the receptors remains to be investigated.

In the past, the approach to eliminate the undesirable side effects of the opiate alkaloids was to design drugs that would have selectivity toward one specific opioid receptor. A classic example is the development of drugs that would have κ -opioid receptor selectivity, because the dysphoric effect of κ -opioid receptor activation would reduce the addictive liability of the drug. Unfortunately, drugs marketed thus far do not exhibit the ultimate property of opiate analgesic, that is, efficacious

pain relief with no side effects. The problem lies mainly with the presence of multiple opioid receptors and the selectivity of the drugs for these receptors. There are attempts to develop bivalent compounds, that is, drug molecules that have two pharmacophores recognizing two different receptors. By bridging an agonist and antagonist together with a spacer arm, the idea is to have the bivalent compound activate one receptor resulting in the pain relief, while the antagonist part of the molecule will inactivate a different receptor resulting in the blunting of the side effects. Such an approach is attractive and shows promise in blocking the tolerance development, but not the other side effects of opiate agonists. Hence, new approaches should be taken in the future for development of pain-management paradigms. With the advent of gene therapy, one could envision the use of receptor engineering in the treatment of pain. If an opioid-receptor mutant could be identified that exhibits distinct phenotype from that of the endogenous receptors, and that this receptor mutant could be delivered to the site of action, that is, substantia gelatinosa of the spinal cord, then activation of such mutants by a drug that normally would not activate the endogenous receptors, for example, an opiate antagonist, would result in pain relief. Such an approach would not only provide specificity, but also would eliminate the side effects of the opiate drugs; but this approach could only be

accomplished when the molecular basis for the action of the multiple opioid receptors is fully elucidated.

Glossary

ORAI The bona fide pore-forming subunit of the store-operated calcium channel, named after the keepers of heaven's gate in Greek mythology. The ORAI proteins have three isoforms, ORAI1, ORAI2, and ORAI3, each of which contains four transmembrane domains.

Store operated calcium entry (SOCE) A calcium ion entry mechanism in the plasma membrane activated by the

depletion of calcium ion from the internal calcium store in the endoplasmic reticulum.

Stromal interaction molecule (STIM) An ER-resident protein responsible for sensing ER calcium depletion via its luminal domain, and communicating with the store-operated ORAI calcium channels in the plasma membrane through its cytoplasmic domain.

Brief History and I_{CRAC}

Ca^{2+} is a universal and versatile messenger that regulates diverse biological processes, including triggering of life during fertilization and the perishing of cells through programmed cell death or apoptosis. To control the speed, amplitude, and spatio-temporal pattern of cytosolic Ca^{2+} signals, the cell draws on Ca^{2+} from two sources: the extracellular space where free Ca^{2+} concentration is as high as 1–2 mM and internal Ca^{2+} stores, mainly the endoplasmic reticulum (ER), with free luminal Ca^{2+} at a level of ~ 400 – 600 μ M. The cytoplasmic-free Ca^{2+} concentration ($[Ca^{2+}]_i$) in resting cells is tightly maintained at 50–100 nM through a long-term balance between Ca^{2+} influx and extrusion of Ca^{2+} via plasma membrane Ca^{2+} -ATPases (PMCA) and, in some cells, exchangers. In the short term, transient Ca^{2+} signals are shaped by pumping Ca^{2+} into the ER lumen through the sarco-endoplasmic Ca^{2+} -ATPases (SERCAs), by sequestering Ca^{2+} in mitochondria, and by Ca^{2+} binding to sites in proteins and other molecules. Changes in $[Ca^{2+}]_i$ can be initiated by the ligand engagement of plasma membrane receptors coupled to phospholipase C (PLC), an enzyme family that hydrolyzes the membrane phospholipid phosphatidylinositol-4,5-bisphosphate to produce the second messengers diacylglycerol and inositol-1,4,5-trisphosphate (IP_3). IP_3 subsequently binds to the IP_3 receptor in the ER membrane and triggers the release of Ca^{2+} from the ER lumen into the cell cytoplasm. In general, release of Ca^{2+} from internal stores is not sufficient by itself to promote long-term responses, such as the activation of nuclear factor of activated T cells (NFATs) and cytokine production by immune cells. With an ongoing stimulus, the initial rise of $[Ca^{2+}]_i$ triggered by store depletion is often followed by a second, sustained elevation of intracellular Ca^{2+} level (Figure 1). By the 1980s, the development of membrane-permeable Ca^{2+} indicator dyes and the patch-clamp technique provided the tools to examine these processes mechanistically.

In 1986, Putney proposed that the depletion of ER Ca^{2+} stores could evoke sustained Ca^{2+} influx across the plasma membrane of nonexcitable cells. Physiologically, this sustained Ca^{2+} influx is part of a chain of events following receptor activation, but it is a process separable experimentally from

receptor engagement, generation of second messengers, or the rise in $[Ca^{2+}]_i$. Observations on many types of cells were crystallized into the notion of capacitative Ca^{2+} entry, later termed store-operated Ca^{2+} entry (SOCE). Within a few years, electrophysiological studies established that T lymphocytes and mast cells indeed express Ca^{2+} channels that are opened in response to store depletion. The direct link between store depletion and Ca^{2+} current was demonstrated by use of pharmacological triggers such as the Ca^{2+} ionophore ionomycin, which empties the ER stores but bypasses receptor activation and the generation of IP_3 ; thapsigargin and other inhibitors of the SERCA pump, which have a similar effect by upsetting the balance between passive leakage of Ca^{2+} from ER stores and active uptake; and the chelator tetrakis-(2-pyridylmethyl)ethylene-diamine (TPEN), which lowers free Ca^{2+} concentration by binding Ca^{2+} in the ER lumen, without causing any net movement of Ca^{2+} out of the ER. The inward rectifying current recorded from T cells and mast cells, known as calcium release-activated calcium current (I_{CRAC}), is distinguished from other Ca^{2+} currents by the following unique fingerprint (also see the comparison in Table 1):

- I_{CRAC} is solely triggered by physiological stimuli leading to the partial depletion of ER Ca^{2+} stores or by experimental manipulations that mimic store depletion.
- The calcium release-activated calcium channel (CRAC) is highly selective for Ca^{2+} over monovalent cations such as Na^+ and K^+ , with a permeability ratio (P_{Na}/P_{Ca}) of $>1000:1$. This property sets the CRAC channel apart from many other Ca^{2+} -permeable channels, such as the transient receptor potential C (TRPC) channels that have a P_{Na}/P_{Ca} between 0.1:1 and 10:1.
- The single CRAC channel Ca^{2+} current amplitude is estimated to be as low as 4–5 fA, or roughly 10^4 Ca^{2+} ions flowing through the channel per second, at -110 mV transmembrane potential and 20 mM external Ca^{2+} , representing a stronger electrochemical force driving Ca^{2+} influx than the channel would experience physiologically. In comparison, the L-type Ca^{2+} channel, which resembles the CRAC channel in its Ca^{2+} selectivity, can carry $\sim 5 \times 10^5$ Ca^{2+} ions per second across the plasma membrane.

Figure 1 Scheme of SOCE mediated by the ORAI1–STIM1 pathway in lymphocytes. Upon engagement of immunoreceptors, the production of IP₃ leads to the activation of IP₃R and release of Ca²⁺ from internal stores. The decrease of ER Ca²⁺ concentration is subsequently sensed by the EF-hand-containing ER Ca²⁺ sensor STIM1, which in turn activates the ORAI1 CRAC channels through its interaction with the pore-forming subunit ORAI1, followed by a second phase of intracellular Ca²⁺ elevation and further activation of downstream effectors, including calcineurin, NFAT, and NFAT-dependent gene expression.

Table 1 Comparison of biophysical properties of the ORAI1 channel, L-type Ca_v channels, and TRPC channels

	<i>ORAI1</i> channel	<i>L-type Ca_v</i> channel	<i>TRPC</i> channel
Unitary conductance	<0.1 pS	3–20 pS	16–66 pS
Ion selectivity (P _{Ca} /P _{Na})	>1000	>1000	0.1–10
Modes of activation	Store operated	Voltage operated	Inositol lipid breakdown

- The CRAC channel exhibits distinct fast (100 ms timescale) and slow inactivation processes in response to the elevation of intracellular Ca²⁺.

Molecular Basis of SOCE: Roles of Stromal Interaction Molecules (STIM) and ORAI

The discovery of I_{CRAC} led to intense interest in the molecular identity of channels and regulators involved in SOCE. However, it was only with the advent of RNA interference (RNAi)-screening techniques that two protein families were clearly implicated in SOCE, the ER-resident stromal interaction molecules (STIM1 and STIM2) and the plasma-membrane ORAI proteins (ORAI1–ORAI3). Within these families, it is primarily STIM1 and ORAI1 that underpin I_{CRAC} in T lymphocytes and mast cells.

STIM Proteins

Early studies of STIM1 had provided evidence that STIM1 was a tumor suppressor or a transmembrane protein of bone marrow stromal cells involved in communication with B cells, and had placed a fraction of STIM1 in the plasma membrane. In 2005, limited RNAi screens performed with *Drosophila* S2 cells and HeLa cells identified *Drosophila* Stim and human STIM1 and STIM2 as proteins whose depletion diminished SOCE. STIM1 has an ER-luminal domain of ~22 kDa after cleavage of its signal peptide, a single transmembrane segment, and a cytoplasmic domain of ~51 kDa (Figure 2(a)). In contrast to expectations from the earlier work, STIM1 is predominantly localized in the ER, and it is generally accepted that ER-resident, but not plasma membrane STIM1, controls CRAC channel opening. ER-resident STIM1 carries out two basic functions: serving as a sensor of free Ca²⁺ in ER stores via its ER-luminal domain and communicating to ORAI Ca²⁺ channels in the plasma membrane through its cytoplasmic domain.

STIM1 ER-luminal domain: Sensing ER Ca²⁺ depletion and initiating STIM1 oligomerization

The ER-luminal portion of STIM1 contains an ER retention sequence, a canonical Ca²⁺-binding EF-hand, and a sterile alpha motif (SAM) domain. The Ca²⁺ sensing by STIM1 in cells is conveniently indicated by the redistribution of the diffusible STIM1 to form numerous individual spots, or puncta, adjacent to the plasma membrane following depletion of ER Ca²⁺ stores. The measured dissociation constant for Ca²⁺ binding to the STIM1 luminal domain is ~500–600 μM, a

Figure 2 Structure and properties of STIM1. (a) Domain architecture of human STIM1, including the signal peptide (S), the canonical Ca²⁺-binding EF-hand 1 (cEF1), the hidden atypical EF-hand 2 (hEF2), the sterile alpha motif (SAM) domain, the transmembrane domain (TM), three putative coiled-coil regions (cc1, cc2, and cc3), the proline- and serine-rich region, and the polybasic lysine-rich region at the C terminus. The luminal EF-SAM fragment with determined NMR structure (panel c) is indicated. The numbers above the diagram indicate the approximate boundaries of the domains. (b) Sequence conservation in the cytoplasmic fragment of STIM1. The horizontal black bar represents the human STIM1 sequence, with gaps introduced to maintain alignment with human STIM2 or STIM proteins from other species as indicated. Vertical green lines indicate sequence identity between human STIM1 and STIM2 at corresponding positions; vertical magenta or blue lines indicate sequence identity among human STIM1 and at least four of five fish orthologs, or among human STIM1 and at least two of three insect STIM proteins, respectively. (c) Solution structure of the EF-SAM fragment determined by NMR spectroscopy. Cylinders represent alpha helices. (magenta, the canonical Ca²⁺-binding EF-hand 1 with bound Ca²⁺ (yellow sphere); beige, the hidden atypical EF-hand 2; green, the SAM domain). Two views related by a 90° rotation are shown. (a) Adapted from Hogan PG, Lewis RS, and Rao A (2010) Molecular basis of calcium signaling in lymphocytes: STIM and ORAI. *Annual Review of Immunology* 28: 491–533. (b) Adapted from Zhou Y, Meraner P, Kwon HT, et al. (2010) STIM1 gates the store-operated calcium channel ORAI1 *in vitro*. *Nature Structural & Molecular Biology* 17: 112–116. (c) Adapted from Stathopoulos PB, Zheng L, Li GY, Plevin MJ, and Ikura M (2008) Structural and mechanistic insights into STIM1-mediated initiation of store-operated calcium entry. *Cell* 135: 110–122.

value that is comparable to the free Ca²⁺ concentration in the ER lumen.

An NMR structure of a recombinant fragment of human STIM1 encompassing most of the STIM1 luminal domain (residues 58–201, termed 'EF-SAM', Figure 2(c)) reveals the presence of a second hidden non-Ca²⁺-binding EF-hand paired with the upstream canonical EF-hand. The paired EF-hands engage and stabilize the helix-rich SAM domain through extensive hydrophobic interactions. The EF-SAM domain readily undergoes a Ca²⁺-dependent transition from monomer to a mixture of dimers and larger aggregates *in vitro*: with Ca²⁺ bound, it exists as monomer in solution, whereas the dissociation of Ca²⁺ triggers unfolding and oligomerization of the EF-SAM domain. Mutations predicted to disable Ca²⁺ binding or to disrupt the interaction between the second

EF-hand and the SAM domain led to unfolding of the EF-SAM domain *in vitro* and caused constitutive formation of STIM1 puncta and Ca²⁺ influx in cells. Further, induced oligomerization of an engineered STIM1, in which the native luminal domain had been replaced by domains that will interact in the presence of a rapamycin analog, also triggered formation of puncta and activation of I_{CRAC}. The dimerization or oligomerization of STIM1 in cells during Ca²⁺ sensing is evidenced by increased fluorescence resonance energy transfer (FRET) between cyan fluorescent protein (CFP)-STIM1 donor and yellow fluorescent protein (YFP)-STIM1 acceptor upon store depletion, a step that precedes the appearance of STIM1 puncta near the plasma membrane. Thus, both *in vitro* and cell-based assays convincingly establish the physiological role of the STIM1 luminal domain in sensing changes in ER luminal

Figure 3 Cartoon representation of STIM1. The cytoplasmic fragment of STIM1 contains three putative coiled-coil regions (cyan), a proline- and serine-rich region (red), and a polybasic tail (blue). The coiled coil is able to span a distance of 8–17 nm that separates ER from plasma membrane. Adapted from Hogan PG, Lewis RS, and Rao A (2010) Molecular basis of calcium signaling in lymphocytes: STIM and ORAI. *Annual Review of Immunology* 28: 491–533.

Ca^{2+} concentration and in initiating the oligomerization of STIM1 and its movement to puncta.

STIM1 cytoplasmic domain: Coupling to and opening ORAI1 Ca^{2+} channel

The STIM1 cytoplasmic domain (residues 233–685) consists of three putative coiled-coil regions, a proline/serine-rich domain, and a poly-basic segment at the C terminus (Figure 3). This domain is responsible for direct coupling to ORAI1 and for triggering opening of the ORAI1 channel. The C-terminal poly-basic segment is believed to contribute to STIM1 targeting to ER-plasma membrane contacts by an interaction with negatively charged polyphosphoinositides such as PIP_2 and PIP_3 . N-terminal and C-terminal truncations of the STIM1 cytoplasmic domain have further mapped a minimal fragment of STIM1 that can directly interact with and activate overexpressed ORAI1. The minimal region, termed ‘STIM1-ORAI activating region (SOAR), CRAC activation domain (CAD), or ccb9, encompasses roughly residues 344–442, and overlaps with the second and third predicted coiled coils. Notably, the minimal region effective in activating CRAC current is positioned approximately 110 residues past the single transmembrane segment that tethers STIM1 to the ER. Thus, one likely function of the

first coiled coil is to span the $\sim 8\text{--}17$ nm separating ER from plasma membrane, but this does not rule out additional functions, such as participation in a conformational change that enables STIM1 to activate CRAC channels. The STIM1 cytoplasmic region and some of its fragments form dimers or tetramers in solution and bind directly to peptide segments in both the N- and C- terminal cytoplasmic regions of ORAI. Binding of recombinant STIM1 is sufficient to open the channel.

STIM2: Maintaining basal cytoplasmic and ER Ca^{2+} levels

The other isoform of human STIM proteins, STIM2, resembles STIM1 in its primary sequence (Figure 2(b)), domain architecture, and cellular localization. It also echoes the basic functional properties of STIM1. Recombinant STIM2 luminal domain binds Ca^{2+} with an affinity suitable for sensing ER Ca^{2+} levels and undergoes Ca^{2+} -dependent monomer-to-oligomer transition *in vitro*. In mammalian cells, STIM2 redistributes to puncta at ER-plasma membrane appositions, and activates ORAI1 channels when the proteins are coexpressed. However, although STIM2 can engage in the same signaling pathway as STIM1, in many cases it gives little evidence of contributing to SOCE. STIM2 at endogenous levels does not support SOCE in STIM1^{-/-} T cells and even overexpression of STIM2 only partially rescues SOCE. STIM2 redistributes in response to release of Ca^{2+} from ER stores in HEK293 cells responding to physiological stimulation, but it does not efficiently activate Ca influx. The established role for STIM2 is to maintain basal cytoplasmic and ER Ca^{2+} levels, an apparently humble occupation, yet absence of STIM2 has dramatic physiological and pathophysiological effects. STIM2^{-/-} murine T cells display severe deficits in the sustained translocation of NFAT to the nucleus and in cytokine production. In addition, STIM2 evidently has a key role in hypoxic neuronal cell death. STIM2^{-/-} neurons show increased survival under hypoxic conditions, and STIM2^{-/-} mice are protected from ischemia-induced neurological damage.

ORAI Proteins

ORAI1 was pinpointed as necessary for I_{CRAC} through the convergence of genome-wide *Drosophila* RNAi screens and a genetic approach that traced a familial severe combined immunodeficiency (SCID) syndrome to a point mutation in ORAI1. Mutations that altered ion selectivity indicated that ORAI was a CRAC channel subunit, and it is now considered to be the only essential channel subunit. The ORAI1 channel opens in response to the signal conveyed by STIM1, conducts Ca^{2+} selectively, and further communicates to downstream effectors.

Membrane topology and assembly of ORAI1

The human ORAI proteins have three isoforms, ORAI1, ORAI2, and ORAI3, among which ORAI1 is most thoroughly studied. ORAI1 monomer is a $\sim 33\text{-kDa}$ plasma membrane proteins with four transmembrane segments and intracellular N and C termini (Figure 4). The membrane topology of ORAI was established by (1) the intracellular location of N-terminal and C-terminal epitope tags and the extracellular location of an epitope tag introduced into the TM3–TM4 loop, (2) verification that an N-glycosylation site in the TM3–TM4 loop is

Figure 4 A snake-like diagram of human ORAI1. ORAI1 is a plasma membrane protein with four transmembrane (TM) segments. E106 (red) in TM1 is the main Ca^{2+} -binding site and directly coordinates Ca^{2+} ions traversing the channel. Another conserved glutamate residue E190 (orange) in TM3 has been implicated in Ca^{2+} selectivity, but does not directly coordinate Ca^{2+} ions. Disease-associated mutations R91W, which affect channel function, and A103E, and L194P, which affect protein stability, are shown in blue. The hexagonal structure attached to N223 (green) indicates the glycosylation site. Adapted from Hogan PG, Lewis RS, and Rao A (2010) Molecular basis of calcium signaling in lymphocytes: STIM and ORAI. *Annual Review of Immunology* 28: 491–533.

glycosylated and therefore extracellular, and (3) evidence that substitutions in the TM1–TM2 loop alter channel blockade by extracellular lanthanide ions.

ORAI1 is generally thought to assemble into a tetrameric CRAC channel. The best evidence comes from electrophysiological studies on channels made from concatenated ORAI1 monomers. A tandem tetramer of ORAI1 is functional as a selective Ca^{2+} channel, and fails to incorporate additional ORAI monomers when challenged by coexpression of a dominant negative ORAI1 subunit. The tetrameric structure of the ORAI1 channel is further corroborated by single-molecule photobleaching studies of green fluorescent protein-tagged *Drosophila* Orai and human ORAI1 channels sparsely expressed in the plasma membrane, in which four individual bleaching steps were often resolved, albeit only for activated Orai in the case of the *Drosophila* channel. In addition, chemical cross-linking studies indicate that both *Drosophila* Orai and human ORAI1 can form tetramers in the native membrane.

Structural determinants of Ca^{2+} permeation, selectivity, and gating

Like other ion channels, ORAI1 provides an energetically favorable ion conduction pathway that allows specific ions to traverse the lipid bilayer. The pore of the ORAI1 channel is

capable of selectively discriminating among different ions, particularly choosing Ca^{2+} over the more abundant Na^{+} of physiological solutions. And, as with many other channels, pore opening and closing (gating) of the ORAI1 channel is tightly and precisely regulated. Accelerated biochemical and electrophysiological studies have started to provide insights into the pore architecture and gating of this unique Ca^{2+} channel:

- The ORAI1 channel is assembled as a tetramer or a higher oligomer with the transmembrane helix 1 (TM1) centrally located. One face of each TM1 helix lines the pore.
- The short loop between TM1 and TM2 forms a flexible outer vestibule above the mouth of the pore. La^{3+} , but not Ca^{2+} , can bind tightly to this loop.
- The negatively charged glutamate residue E106 in TM1 plays a key role in Ca^{2+} permeation and contributes to the high Ca^{2+} selectivity of ORAI1 channels. Most likely, four glutamate residues at position 106 of a tetrameric ORAI channel directly coordinate Ca^{2+} ions traversing the channel, in much the way that the EEEE locus in the P-loop coordinates Ca^{2+} in the pore of the L-type voltage-gated Ca^{2+} channel. The pore (with an estimated diameter of 3.8 Å) sharply narrows at or below the level of E106, thereby shaping the ion selectivity.

- Although a conserved glutamate residue (E190) in TM3 has been implicated in Ca^{2+} selectivity, it is not directly involved in the coordination of Ca^{2+} . The E190Q substitution alters ion selectivity and widens the pore size from 3.8 to 7.0 Å, but probably does so through an allosteric change in the selectivity filter.
- STIM1 directly gates ORAI1 channels by physically interacting with both the C-terminal region of ORAI1 and an N-terminal segment immediately preceding TM1. Considerable circumstantial evidence suggests that this N-terminal segment may be involved in channel gating. A movement of TM1 might contribute to the channel gating, through either a displacement of TM1 or a reorientation of TM1 that brings E106 into a geometry allowing ions to travel through the channel. A deep and detailed understanding of gating mechanism, nevertheless, requires the determination of the atomic structure of ORAI1 and/or the ORAI1–STIM1 complex.

Orai2 and Orai3

The other two isoforms of ORAI proteins, ORAI2 and ORAI3, share remarkable sequence similarity to ORAI1 in the four transmembrane segments. Key residues equivalent to E106 and E190 in ORAI1 that contribute to the Ca^{2+} selectivity are conserved in these two proteins. In addition, the N- and C-terminal segments implicated in the STIM1–ORAI1 interaction are conserved. These channels are selective for Ca^{2+} over Na^+ . However, they differ in more subtle channel properties, such as the prominence of fast inactivation and the response to the pharmacological agent 2-aminoethoxydiphenyl borate (2-APB). For example, 2-APB at low concentrations has been found to activate store-operated ORAI1 and ORAI2 currents, but 2-APB at 75 μM is an inhibitor. By contrast, 2-APB at 75 μM directly activates the ORAI3 channel, independent of either Ca^{2+} store depletion or STIM1.

ORAI3 channels account for store-operated Ca^{2+} entry in human MCF7 adenocarcinoma cells. ORAI proteins are also capable of forming heteromeric channels. A pentameric assembly of ORAI1 and ORAI3 subunits is reported to form arachidonate-regulated Ca^{2+} -selective (ARC) channels that respond to arachidonic acid rather than to store depletion. It has also been proposed that ORAI proteins form heteromeric channels that are less Ca^{2+} selective than the homomeric channels. The full repertoire and physiological function of channels that incorporate ORAI2 and ORAI3 subunits remain to be explored.

STIM–ORAI Signaling

That ORAI and STIM are major players in the SOCE pathway has been established by (1) reconstitution of SOCE and CRAC current in the SCID T cells by expression of ORAI1; (2) production of monster Ca^{2+} -selective currents with the characteristics of I_{CRAC} when STIM1 and ORAI1 are overexpressed in mammalian cells; (3) evidence that various fragments derived from the STIM1 cytoplasmic domain are capable of decorating the plasma membrane and activating constitutive CRAC currents in ORAI1-expressing cells; and (4) successful recapitulation of Ca^{2+} flux through the pore of

ORAI1 channels induced by the STIM1 cytoplasmic fragments *in vitro*. Through extensive biochemical, structural, electrophysiological, and cell biological studies in the past 5 years, a wealth of information has been accumulated to support the following model of ORAI channel activation (Figure 5) and regulation.

Steps in SOCE

In the resting state, STIM1 is homogeneously distributed throughout the ER, whereas ORAI is distributed throughout the plasma membrane. Upon store depletion, the dissociation of Ca^{2+} from the STIM1 canonical EF-hand leads to partial unfolding and exposure of hydrophobic regions in the STIM1 luminal domain, which ultimately causes the oligomerization of STIM1. STIM1 oligomers then migrate toward ER-plasma membrane appositions to form STIM1 puncta within tens of seconds. This step is independent of ORAI expression and involves at least the interaction of the STIM1 polybasic C terminus with PIP_2 and PIP_3 in the plasma membrane. Subsequently, STIM1 oligomers recruit ORAI1 to puncta, most likely through a direct protein–protein interaction involving the ORAI C-terminus and a cytosolic region of STIM1. Finally, STIM1 oligomers open ORAI channels, possibly through a physical interaction with a membrane-proximal N-terminal segment (contained within residues 65–91) of ORAI1. The stoichiometry of the STIM–ORAI complex remains an open question that might be eventually resolved through structural determination of the conformations and oligomerization states of full-length STIM1 and ORAI1.

Modulation of STIM–ORAI Signaling

Influx of Ca^{2+} results in a high local Ca^{2+} concentration near the cytoplasmic opening of the ORAI channel. A feedback inhibition mechanism known as ' Ca^{2+} -dependent fast inactivation' limits Ca^{2+} overloading into the cells. This process is demonstrated experimentally as a decline in I_{CRAC} over 200–500 ms during large hyperpolarizing voltage steps that trigger substantial Ca^{2+} influx. The molecular determinants of this regulatory mechanism include (1) a stretch of negatively charged sequence C-terminal to the SOAR or CAD domain in STIM1, (2) a calmodulin-binding site in the membrane-proximal N-terminal region of ORAI1 that can be engaged by calmodulin in a Ca^{2+} -dependent manner, (3) the intracellular loop of ORAI1 that links TM2 and TM3 of ORAI1, and (4) the selectivity filter itself.

Ca^{2+} influx must be tightly regulated, and one regulator of SOCE has been identified through a proteomic approach. The protein termed 'CRACR2A' is a cytosolic Ca^{2+} -sensing protein that contains two EF-hand domains and extensive coiled-coil regions. CRACR2A has been shown to facilitate the clustering of ORAI1 and STIM1 in puncta through direct interactions with both ORAI1 and STIM1. The ternary complex falls apart when the cytosolic Ca^{2+} rises. Given the limited amounts of ORAI and STIM in a physiological context, it is speculated that CRACR2A plays a role in stabilizing the active CRAC channel complex upon store depletion.

The only reported physiological case in which SOCE is strongly suppressed or inactivated is during cell division,

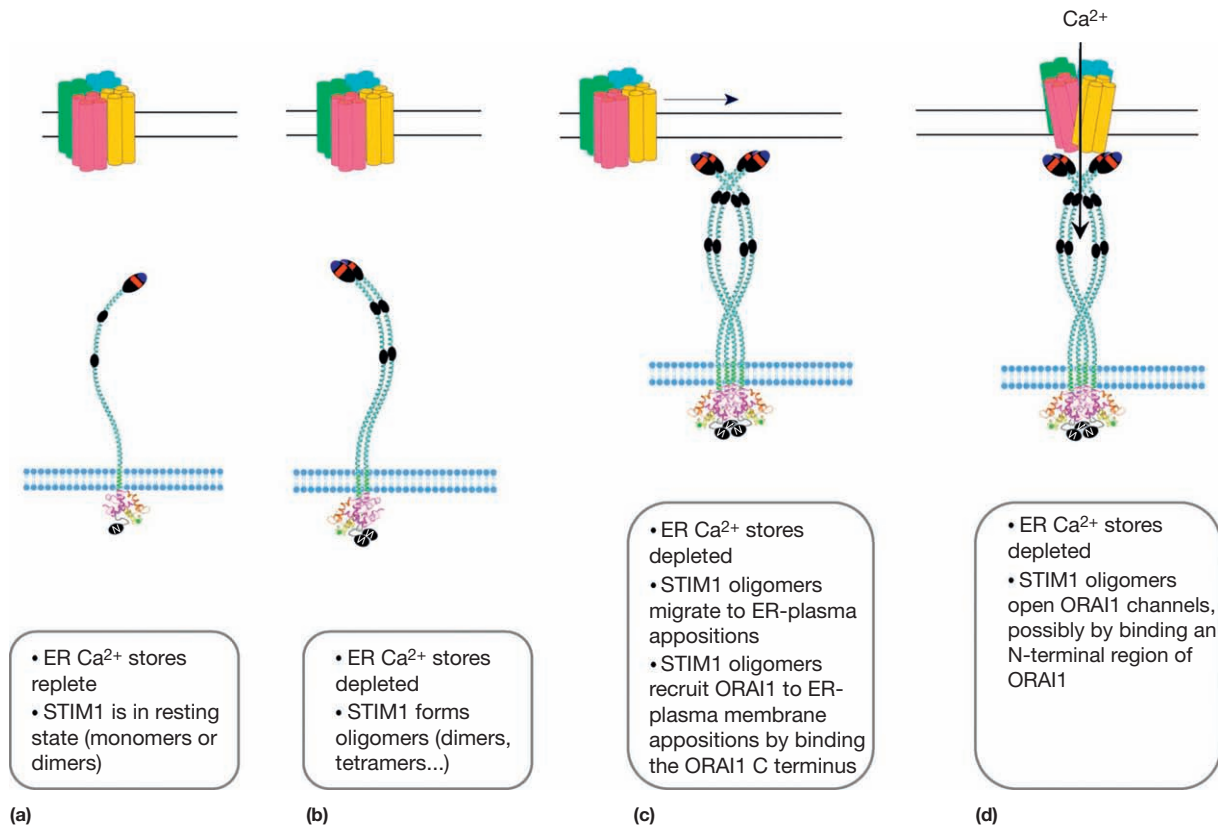

Figure 5 Major steps in SOCE mediated by ORAI1 and STIM1. (a) Schematic of STIM1 and ORAI1 in resting state, when ER Ca^{2+} stores are replete. Although their oligomerization states in resting cells are not yet fully defined, STIM1 is depicted as a monomer and ORAI1 as a tetramer for convenience. (b) STIM1 forms oligomers when ER Ca^{2+} stores are depleted. Again, the exact oligomerization state of STIM1 in activated cells remains unknown. (c) STIM1 oligomers undergo redistribution and migrate toward ER-plasma membrane appositions. STIM1 oligomers further recruit ORAI1 to ER-plasma membrane appositions by directly interacting with the C-terminal tail of ORAI1. (d) STIM1 oligomers open ORAI1 channels possibly through a second contact with an N-terminal region of ORAI1. Adapted from Hogan PG, Lewis RS, and Rao A (2010) Molecular basis of calcium signaling in lymphocytes: STIM and ORAI. *Annual Review of Immunology* 28: 491–533.

particularly during the M phase of the cell cycle. One recent study on mitotic HeLa and mitotic HEK293 cells indicates that phosphorylation of STIM1 may account for suppressed SOCE during mitosis. Two mitosis-specific phosphorylation sites in STIM1 (residues S486 and S668) have been mapped by taking a proteomic approach. Substitution of these sites with alanine to prevent phosphorylation has been shown to rescue mitotic SOCE. Nevertheless, results from another study on *Xenopus* oocytes during meiosis argue that phosphorylation cannot be the sole method of SOCE inactivation. In that study, it was shown that both the internalization of ORAI1 and the inhibition of STIM1–STIM1 interaction have a role in uncoupling store depletion from SOCE activation during meiosis.

STIM–ORAI Signaling and Human Disease

CRAC channel function is defective in a few human patients with inherited SCID. T cells from these SCID patients display a marked deficiency in cytokine production, loss of SOCE, loss of I_{CRAC} , and failure of efficient nuclear translocation of NFAT. The genetic basis has been traced back in four families to mutations in either ORAI1 or STIM1. The identified mutations

in ORAI1 have included a missense loss-of-function mutation (R91W), a frameshift that causes loss of ORAI1 protein expression, and two independent missense mutations, A103E and L194P, that also lead to loss of ORAI1 expression. A fourth inherited immunodeficiency was traced to insertion of an adenine in the third exon of STIM1 that results in a frameshift and premature termination, and absence of STIM1 protein.

Although loss of CRAC channel function is an uncommon cause of primary immunodeficiency, these cases have been illuminating in terms of CRAC channel signaling. Both ORAI1 and STIM1 are widely expressed in different tissues, yet the major clinical consequences of defective CRAC channels are surprisingly limited to the immune system, skeletal muscle, and certain ectodermally derived tissues. The main clinical manifestation of ORAI1 and STIM1 loss-of-function mutations is severe immunodeficiency, marked by frequent and severe infections early in life. The most prominent associated non-immune disorders are a congenital, nonprogressive myopathy, and ectodermal dysplasia. Thus, drug candidates that specifically target the STIM1–ORAI1 pathway have the potential to suppress immune function selectively and may lack the toxicity of current immunosuppressive agents, such as cyclosporine A and FK506.

Organization of the Bacterial Nucleoid

C J Dorman, Trinity College Dublin, Dublin, Republic of Ireland

© 2013 Elsevier Inc. All rights reserved.

Glossary

Chromosome domains Discrete loops of bacterial chromosomal DNA, approximately 10 kilobases in circumference, thought to be pinched closed by domain boundary elements such as nucleoid-associated proteins.

Nucleoid The region of the bacterial cell that is occupied by the genetic material and its associated proteins and RNA. Unlike the nucleus of a eukaryotic cell, the bacterial nucleoid is not bounded by a membrane.

Sigma factor The protein component of bacterial RNA polymerase that recognizes and binds to the transcriptional promoter in DNA, carrying out the isomerization step that converts the closed transcription complex to an open one

during transcription initiation. The sigma factor is ejected from RNA polymerase during the elongation phase of transcription.

Topoisomerase An enzyme that alters the linking number of DNA by a mechanism involving DNA strand cleavage, strand passage, and religation.

Transcription factories (or foci) Accumulations of the most active transcription promoters in the cell (usually the promoters of ribosomal RNA genes) together with RNA polymerase. When RNA polymerase is linked to a fluorescent marker, these accumulations are detectable by microscopy. Rapidly growing bacterial cells typically have two or three of these transcription factories.

Nucleoid-Associated Proteins

The histone proteins in eukaryotes play a critical role in organizing the DNA in the nucleus and in modulating gene expression. When proteins of similar molecular mass were discovered that performed analogous tasks in bacteria, these were initially named 'histone-like' proteins. This name is going out of use, chiefly because its implication of amino acid sequence similarity to eukaryotic histones is misleading. The bacterial proteins are, in general, quite distinct from the histones in their primary structure and are now usually referred to as 'nucleoid-associated proteins', or NAPs. However, both terms may be found in use in the literature, sometimes in the same article.

There are approximately 12 different NAPs in *Escherichia coli* and they form a disparate group of proteins. Some of the better characterized ones are listed in Table 1. NAPs are abundant and contribute to bacterial chromatin through their DNA-binding activities. Some bind to specific sequences in DNA, a trait that is shared with transcription factors. Others have no obvious DNA sequence preferences among the sites to which they bind but interact instead with particular structures, such as curved DNA. Upon binding, the NAPs influence the path of the DNA in different ways. Some, such as the leucine-responsive regulatory protein, Lrp, wrap the DNA, others, such as the integration host factor (IHF), bend the DNA quite severely, while yet others (e.g., H-NS, the histone-like nucleoid-structuring protein) can engage in the formation of DNA-protein-DNA bridges or can polymerize along the DNA (Figure 1). These DNA manipulations lend themselves to the compaction of the DNA in the nucleoid. They are thought to act in concert with molecular crowding and with negative supercoiling of the DNA to reduce the diameter of the nucleoid in ways that allow it to fit in the cell while allowing the DNA to be replicated and to participate in transcription and recombination.

NAPs and Gene Expression

The NAPs influence gene expression in a number of ways, chiefly at the level of transcription, and this, in turn, has consequences for the structure of the nucleoid. NAPs with well-defined binding sites in DNA frequently are discovered to behave as transcription factors, either enhancing or inhibiting the activities of promoters. The Lrp, IHF, and Crp proteins are examples of NAPs that perform this function. The Crp protein is a particularly interesting case because it was described originally as a transcription factor, but more recently has been shown by genome-wide surveys of Crp-DNA interactions to bind to many hundreds of sites across the nucleoid, a characteristic of NAPs.

The DNA-wrapping protein HU does not have a clear consensus binding site in DNA (unlike its close relative IHF), but it can influence transcription through its ability to facilitate the formation of small loops in DNA that promote regulatory interactions at target promoters. The factor for inversion stimulation (Fis) controls the expression of hundreds of genes and is especially important in optimizing the transcription of the genes that code for the translational machinery of the cell. It has the ability to organize local domains of supercoiled DNA and can facilitate transcription through a combination of local DNA topological adjustments and direct interactions with RNA polymerase.

Transcription has the potential to influence the structure of the nucleoid. When a fluorescent protein is attached to RNA polymerase, accumulations of highly transcribed genes can be seen in individual cells by microscopy. These bodies are called 'transcription foci' or 'transcription factories' and they are created by the driving together of the genes and operons that encode the components of the translation machinery of the cell. This happens in cells that are growing rapidly, if growth is halted the foci disperse. The forces that create and maintain the foci are still not fully understood but the phenomenon shows that

Table 1 Major nucleoid-associated proteins of *Escherichia coli*

Protein	Gene	Molecular mass (kDa)	Remarks
Dps	<i>dps</i>	19	Dps (DNA protection, starvation): abundant in stationary phase; also expressed in bacteria experiencing oxidative stress; general DNA-binding activity; does not influence transcription
Fis	<i>fis</i>	11.2	Fis (factor for inversion stimulation): homodimeric DNA-binding protein; binds to degenerate consensus sequence; bends DNA by between 40° and 90°; organizes local DNA topology; multifunctional; and is involved in transcription, DNA replication, recombination, and transposition. Strong growth-phase regulation varies protein number/cell over 200–100 000 range.
H-NS	<i>hns</i>	15.6	H-NS (histone-like nucleoid structuring): oligomeric DNA-binding protein; lacks a consensus sequence for DNA binding but has an affinity for curved DNA; compacts DNA and constrains supercoils; important transcription regulator (usually a repressor); estimated to be 20 000–60 000 H-NS monomers/cell.
HU	<i>hupA</i> <i>hupB</i>	9.5 9.5	HU (histone-like from strain 'U93'): abundant heterodimeric DNA-binding protein; 60 000 dimers/cell; lacks a consensus sequence for DNA binding; can constrain DNA supercoils.
IHF	<i>ihfA</i> <i>ihfB</i>	11.2 10.6	IHF (integration host factor): heterodimeric DNA binding and bending protein; homolog of HU but binds to well-conserved consensus sequence; bends DNA by up to 180°; between 17 000 and 34 000 monomers/cell.
Lrp	<i>lrp</i>	18	Lrp (leucine-responsive regulatory protein): degenerate consensus binding site sequence; 6000 molecules per cell; dimers, octamers, hexadecamers; activity can be modulated by binding leucine.

Figure 1 The impact of nucleoid-associated proteins on DNA structure. NAPs have a variety of effects on the DNA to which they bind and the principal ones are illustrated here. (a) DNA bending results from binding of many proteins, including NAPs such as IHF. This protein is a heterodimer (Table 1) that contacts the DNA at three places. Two beta ribbons extending from the dimer have proline amino acids at their apices that intercalate in the minor groove of the DNA, causing the duplex to bend by up to 180°. The resulting U-turn can facilitate long-range interactions in DNA. (b) DNA wrapping by proteins such as the Lrp protein compact the DNA and also displace other DNA-binding proteins with alternative modes of DNA binding, such as the bridging activity of H-NS. (c) DNA bridging is promoted by proteins such as H-NS that are dimeric and have a discrete DNA-binding domain that can be placed in contact with either different parts of the same DNA molecule (as shown here) or with two separate DNA molecules. The resulting bridge can act as an effective blockade to the movement of RNA polymerase and so impede the process of transcription. (d) Oligomerization of an NAP. The H-NS protein can also bind to a nucleation site from which it oligomerizes along DNA. The resulting protein–DNA complex can impede binding by other proteins, such as RNA polymerase, and so silence gene expression. Recent data suggest that H-NS can cycle between its DNA–protein–DNA bridging and oligomerization modes in response to the intracellular concentration of divalent cations such as magnesium. The physiological significance of this switching is currently unclear.

the nucleoid has a dynamic structure that is subject to remodeling in response to changes in the physiology of the bacterium.

DNA Supercoiling

The DNA in *E. coli* is underwound about its helical axis and this has important consequences for the structure of the nucleoid

and for the molecular transactions that take place within it. Its underwound state places the DNA under torsional stress and it responds by writhing about its own helical axis, creating the supercoiled form of the already coiled duplex. Supercoiling contributes to the compaction of the DNA in the nucleoid.

The tension in the underwound DNA represents a source of energy that can cause parts of the duplex to form single-stranded bubbles due to breakage of the hydrogen bonds

between pairs of bases. This facilitates transcription and other molecular processes that require the DNA to become transiently single stranded. It is important to note that the process of transcription imparts supercoiling to the DNA template, partly explaining why rapidly growing bacteria with highly active genes and operons have DNA that is more underwound than quiescent cells. DNA supercoiling has to be carefully managed so that it is maintained within limits that are optimal for the survival of the cell. Special enzymes called topoisomerases perform this management function (Table 2).

DNA gyrase is a type II topoisomerase that converts relaxed DNA to a negatively supercoiled form by making double-stranded breaks in the DNA duplex and passing an intact portion of the same DNA molecule through the gap, resealing it thereafter (Figure 2). Gyrase uses adenosine triphosphate (ATP) as a source of energy to complete each supercoiling reaction. This links gyrase activity to the ATP-generating processes of the cell, making gyrase activity rise and fall with the metabolic flux. Thus, rapidly growing cells will have an ATP content that is favorable for high levels of gyrase activity; cessation of growth produces cells in which DNA is relaxed.

DNA topoisomerase I opposes the supercoiling activity of DNA gyrase by relaxing negatively supercoiled DNA. It does this through breakage of one DNA strand, allowing the energy stored in the supercoiled DNA to unwind the gapped molecule by a swiveling action (Figure 2). If gyrase activity is absent, topoisomerase I will remove negative supercoils from the DNA in the nucleoid wherever it can, potentially leading to full relaxation of the chromosome.

NAPs and Topoisomerases

When a protein wraps DNA around its surface, it can preserve the supercoiled or writhed path of the DNA while, at the same time, relieving the tension due to the underwinding of the DNA molecule. It is estimated that about half of the DNA in *E. coli* is complexed with protein, leaving the other half to experience the torsional stress associated with underwinding of protein-free DNA. In this way, the NAPs can modulate the consequences of DNA supercoiling. They can also influence the interaction of topoisomerases with DNA. For example,

Table 2 DNA topoisomerases of *Escherichia coli*

Enzyme	Gene	Molecular mass (kDa)	Remarks
Topoisomerase I	<i>topA</i>	97	Type I enzyme; relaxes negatively supercoiled DNA; cuts one strand of DNA and binds to cut site via a 5'-phospho-tyrosine covalent bond; Mg^{2+} dependent.
DNA gyrase (topoisomerase II)	<i>gyrA</i> <i>gyrB</i>	105 (GyrA) 95 (GyrB)	Type II enzyme; negatively supercoils relaxed DNA (requires ATP); relaxes positively supercoiled DNA; makes a transient double-stranded cut in DNA and binds via a 5'-phosphotyrosine bond Mg^{2+} dependent.
Topoisomerase III	<i>topB</i>	73.2	Type I enzyme; can relax negatively supercoiled DNA; decatenase; Mg^{2+} dependent.
Topoisomerase IV	<i>parC</i> <i>parE</i>	75 (ParC) 70 (ParE)	Type II enzyme with strong sequence homology to gyrase; decatenase; relaxes negative supercoils but cannot create them; requires ATP and Mg^{2+} .

Figure 2 Bacterial topoisomerases and DNA supercoiling. DNA gyrase (not shown) creates a double-stranded break (a) in a circular DNA molecule, passes part of the intact molecule through the resulting gap (b), and then reseals the gap (c) introducing a superhelical turn into the molecule. Part of this supercoiled molecule (d) is bound by DNA topoisomerase I which cuts one DNA strand and becomes covalently attached to one site of the single-stranded gap (e) allowing the free end to rotate around the intact strand (f) releasing negative supercoiling by a swiveling action that relaxes the DNA.

the Fis protein can prevent gyrase and topoisomerase I from over-supercoiling or over-relaxing the DNA template, respectively. This protein appears to play a useful buffering function in the nucleoid by helping to optimize supercoiling levels adjacent to key genes, such as those that code for components of the translation apparatus. Fis also regulates the genes that encode gyrase (*gyrA* and *gyrB*) and topoisomerase I (*topA*): it is a repressor of the *gyrA* and *gyrB* genes and has a dual activator/repressor role at *topA*. Finally, the transcriptional promoter that is responsible for expression of the *fis* gene that encodes the Fis protein is activated by DNA supercoiling and inhibited by DNA relaxation.

The Domain Structure of the Nucleoid

Early experiments with DNA-nicking agents indicated that the chromosome of *E. coli* was organized in a series of independent domains within the nucleoid. A nick in one DNA strand at one site might be expected to result in the relaxation of the whole circular supercoiled chromosome through swiveling of the cut strand around the intact one. However, only limited and localized loss of supercoiling was observed, suggesting that isolators of some kind divide the chromosome into domains that are topologically independent. Genetic experiments and investigations using restriction enzymes to cut the genome in known locations have confirmed the existence of chromosomal domains and these are now estimated to have an average length of 10 kilobase pairs. However, it seems clear that the boundaries of these domains are not fixed and that the number of boundaries varies with the growth rate of the cell. Rapidly growing bacteria have about 400 domains but this number declines sharply as growth ceases. Much effort has been expended in attempting to identify the components of the cell that form the domain boundaries. At the time of writing, NAPs are among the leading contenders, with the Fis and H-NS proteins being especially prominent candidates. Their ability to form DNA–protein–DNA bridges adds to their attraction as potential isolators.

It has become apparent very recently that the nucleoid has a superstructure consisting of four macrodomains. These are located around the origin of chromosome replication (OriC), the termination region (Ter), and the flanking regions that connect these two. The MatP protein is associated exclusively with the Ter region, the SImA protein binds within the other three, while the SeqA protein is associated with GATC sequences in the OriC macrodomain. The integration of the macrodomain superstructure with the NAP-associated microdomain structure is currently a subject of intense research.

Bacterial Physiology, DNA Supercoiling, and NAPs

It is clear that the structure of the nucleoid is dynamic and that it varies as bacteria grow. This is not surprising when one considers that the features of the cell that impart structure to the nucleoid (transcription, molecular crowding, DNA supercoiling, and NAPs) are themselves dynamic. Experiments with *E. coli* and related bacteria where the organisms are grown in batch culture with aeration at their optimum temperature for

growth in a medium that supports a generation time of about 20 min reveal that the superhelicity of the DNA undergoes a series of transitions from relaxed in the inoculum to negatively supercoiled during the exponential phase of growth to relaxed again upon the onset of stationary phase. Under the same growth conditions, the population of NAPs changes. As exponential growth begins, the Fis protein increases to 100 000 copies, making it transiently the most abundant NAP in the cell (Table 1). This event coincides with a demand for ribosomes and other parts of the translational apparatus. The promoters of the relevant genes have a dependency on Fis for optimal activity. In addition, Fis can feed back negatively onto the genes coding for gyrase, exerting a braking action on the expression of topoisomerase that introduces negative supercoils into DNA just as their level peaks in the cell. The H-NS protein is expressed at a relatively constant rate throughout growth and inhibits transcription throughout the genome. However, the H-NS-to-DNA ratio is critical and even minor disturbances to this can alter the global gene expression pattern. This omnipresent protein must be opposed if the hundreds of genes that H-NS represses are to be expressed and this is achieved through a wide variety of molecular mechanisms that include a role for the Fis protein as an H-NS antagonist. As the bacteria enter the stationary phase of growth, the levels of Fis decline to negligible values and another NAP, Dps, becomes dominant. This protein, which appears to have no detectable role in controlling transcription, binds to the chromosome and protects it from chemical damage during the pseudohibernation period of late stationary phase. DNA in these cells is relaxed and transcription is generally repressed, except for a special set of stationary-phase-specific genes whose promoters are read by a dedicated stationary phase sigma factor called RpoS, an RNA polymerase component that can function well with a DNA template that lacks the highly energized state that is characteristic of the chromosome in exponentially growing bacteria. Thus, it may be seen that nucleoid structure and cellular physiology are intimately linked and that the features of the nucleoid that influence its structure also affect directly the gene expression program of the cell and vice versa.

Glossary

Dehydrogenase The enzyme that catalyzes electron transfer from a substrate to an acceptor.

E.C. numbers and trivial names Enzymes are classified and numbered by the International Enzyme Commission. In this list, the names of the enzymes are formal names, whereas trivial names are more common names or informal names.

For example, catechol 1,2-dioxygenase is a formal name while pyrocatechase is a trivial name.

Oxidase The dehydrogenase that utilizes molecular oxygen as an immediate electron acceptor.

Oxygenase The enzyme that incorporates molecular oxygen into substrates.

Oxygenases are a group of oxidative enzymes that catalyze the direct addition or fixation of molecular oxygen into various substrates. The terms ‘mono’ and ‘di’ oxygenases are generally assigned to the enzymes catalyzing the incorporation of either one or two atoms of oxygen per mole of substrate, respectively. Prior to the discovery of oxygenases in 1955, the essential characteristics of biological oxidation processes was believed to be the removal or transfer of electrons or hydrogen atoms from a substrate to an appropriate acceptor. These enzymes were termed ‘dehydrogenases’ and when oxygen molecules serve as the immediate electron acceptor, the enzymes have been called ‘oxidases’. Functionally, dehydrogenases and oxidases are mainly involved in energy metabolism whereas oxygenases play major roles in the anabolism and catabolism of biological materials as well as synthetic compounds.

Background

In 1932, Professor Heinrich Wieland, a German Nobel laureate, authored a book entitled *On the Mechanism of Oxidation*, in which he proposed the famous ‘dehydrogenation theory’. According to this theory, the principle of biological oxidation processes is the activation and transfer of hydrogen atoms, or their equivalent, from the substrate molecule to an appropriate acceptor such as coenzymes and various dyes. Oxygen molecules may, in some instances, serve as the immediate electron acceptor, and if so, then these enzymes are termed ‘oxidases’. Thus, according to Professor Wieland, molecular oxygen accepts hydrogen atoms and is reduced to water or hydrogen peroxide. However, it is never incorporated into the substrate. When the overall reaction is envisaged as the addition of oxygen, the oxygen atoms are always derived from water molecule rather than from atmospheric oxygen. For example, when aldehydes are converted to acids, aldehydes are hydrated first and then dehydrogenation occurs so that the sum is the addition of oxygen to the substrate X to form XO, but this oxygen atom is derived from water rather than from molecular oxygen. Thus, the direct addition of molecular oxygen to a substrate was considered completely irrelevant to biological oxidation.

In 1955, a set of experiments was performed in which pyrocatechase from a pseudomonad was incubated with its substrate catechol and a heavy oxygen isotope, ^{18}O (oxygen-18), the latter being in its molecular form in air in one flask or in the form of water in the other. The product, muconic acid, was isolated and analyzed for its ^{18}O content by mass spectrometry. Contrary to the then generally held belief, the results clearly demonstrated that the oxygen atoms incorporated into the product molecules were derived exclusively from molecular oxygen and not from the oxygen of the water molecule. Concurrently and independently, the phenolase complex of the mushroom was shown to incorporate one atom of molecular oxygen into a substrate, 3,4-dimethylphenol, to form 4,5-dimethylcatechol; whereas the other atom of oxygen was reduced to water. These findings together with subsequent work by others established that oxygen fixation did occur in biological systems, and revealed a new biological role of molecular oxygen; thus, the new concept of biological oxygenation was introduced. These enzymes that catalyze the direct incorporation of molecular oxygen were then named oxygenases. At first, these oxygenase reactions were generally thought to be rather unusual and were limited to only primitive living organisms such as soil bacteria or mushrooms. It took several years before the ubiquitous existence of oxygenases was confirmed in many laboratories; during that time, a large number of oxygenases were isolated from animals, plants, and microorganisms and were shown to play important roles in the metabolism of various nutrients, hormones, and neurotransmitters as well as synthetic compounds.

Nomenclature, Classification, and General Properties of Oxygenases

Dioxygenases

Dioxygenases are defined as enzymes catalyzing reactions in which both atoms of molecular oxygen are incorporated into substrates. In many instances where one substrate can act as the oxygen acceptor, the term ‘intramolecular dioxygenase’ may be used; pyrocatechase (catechol 1,2-dioxygenase) (EC 1.13.11.1) is a typical example. The dioxygenases acting upon two

acceptor substrates may be referred to as 'intermolecular dioxygenases'. One of the two substrates for the latter type has so far been invariably 2-oxoglutarate. Hypoxia-inducible factor 1 is a global regulator of cellular and systemic O_2 homeostasis in animals. Prolyl hydroxylase, also known as procollagen-proline: α -ketoglutarate 4-dioxygenase (EC 1.14.11.2), the enzyme that hydroxylates specific prolyl residues of the collagen chains during their translation and requires 2-oxoglutarate as a co-substrate in addition to ascorbate and Fe^{2+} , serves as an oxygen sensor. More recent evidence indicates that asparaginyl hydroxylase that hydroxylates the asparagine residues by a similar mechanism also serves as a direct oxygen sensor. A third class of dioxygenases include various enzymes that require nicotinamide adenine dinucleotide (NADH) or nicotinamide adenine dinucleotide phosphate (NADPH) as an electron donor. Although it is quite possible that reactions of this class may involve a simple dioxygenation reaction followed by a reductive step, these two processes may be coupled in such a way as to justify a separate category. The formation of catechol from anthranilate is an example of this type of reaction.

Prostaglandin endoperoxide synthase (EC 1.14.99.1) is a unique intramolecular dioxygenase catalyzing the sequential addition of two oxygen molecules to a substrate molecule arachidonic acid to produce prostaglandin G_2 followed by the peroxidase reaction to generate prostaglandin H_2 . This enzyme is also called cyclooxygenase, abbreviated as COX, and is of great clinical significance as discussed below.

Some dioxygenases, such as tryptophan 2,3-dioxygenase, contain heme as the sole prosthetic group; whereas others, such as pyrocatechase, contain nonheme iron, or like quercetinase, contain copper as the prosthetic group.

Monooxygenases

Monooxygenases are defined as a group of enzymes that catalyze the incorporation of one atom of molecular oxygen into a substrate, with the other being reduced to water. Therefore, these enzymes are sometimes referred to as mixed function oxidases or mixed function oxygenases. The electron donors that serve as coenzymes for these enzymes include reduced forms of pyridine nucleotides, flavin nucleotides, cytochromes, ascorbic acid, and pteridine derivatives. In some cases, the substrate itself may serve as an electron donor.

Internal Monooxygenases

The simplest type of monooxygenase catalyzes the incorporation of a single atom of molecular oxygen concomitant with the reduction of the other oxygen atom by electrons derived from the substrate. As the reducing agent is internally supplied, these enzymes may be referred to as internal monooxygenases. The first of these enzymes to be crystallized was the lactate oxidative decarboxylase from *Mycobacterium phlei*. This enzyme catalyzes the conversion of lactate to acetate with the incorporation of one atom of oxygen into acetate, the evolution of 1 mol of CO_2 , and the reduction of one atom of oxygen to water.

External Monooxygenases

Although the internal monooxygenases do not require external reducing agents, more common types of monooxygenases require various types of electron donors. The electron donor (DH_2) serves as a basis for the subclassification of external monooxygenases. Some examples are as follows:

1. *Flavoprotein monooxygenases with reduced pyridine nucleotides as DH_2 .* Salicylate 1-monooxygenase, a flavoprotein, is an example of this type of enzyme and catalyzes the formation of catechol from salicylate.
2. *Heme-containing monooxygenases.* Aryl 4-monooxygenase (liver microsomal cytochrome p-450) catalyzes the hydroxylation of a variety of substrates with reduced flavin as DH_2 .
3. *Heme-containing monooxygenases with a reduced iron-sulfur protein as DH_2 .* Camphor 5-monooxygenase is a typical example of this type of enzyme.
4. *Pteridine-linked monooxygenases.* Phenylalanine-4-monooxygenase catalyzes the formation of tyrosine from phenylalanine. Nitric oxide (NO) is a ubiquitous bioactive substance and a unique messenger molecule. It is synthesized from L-arginine by NO synthase (NOS), (EC 1.14.13.39), a unique monooxygenase that catalyzes two consecutive monooxygenase reactions and that requires NADPH, tetrahydrobiopterine, heme, and Ca^{2+} /calmodulin and contains flavin adenine dinucleotide and flavin mononucleotide. The product of the reaction is L-citrulline.
5. *External monooxygenases with ascorbate as DH_2 .* Dopamine β -monooxygenase is an example of this type of enzyme.
6. *External monooxygenases with another substrate as DH_2 .* Monophenol monooxygenase is an example of this type. In this case, dopa may be considered as the electron donor in the reaction.

Chemistry of Oxygen Fixation Reactions

Molecular Oxygen as a Substrate

Oxygenases utilize two different species of substrate, namely, molecular oxygen and the oxygen acceptor, which is called the substrate and may be either an organic or an inorganic compound. It has not yet been clarified whether gaseous oxygen or oxygen dissolved in water is utilized by these enzymes. It is generally believed that the latter type of oxygen is different from the former. In water, oxygen is considered to exist largely in a dimerized form, O_2-O_2 because of its biradical nature, and probably forms a charge transfer complex with a water molecule. Whatever form is taken by the oxygen dissolved in water, the type of oxygen that serves as a substrate for oxygenases is in rapid equilibrium with gaseous oxygen under normal experimental conditions and can be clearly distinguished through the use of $^{18}O_2$ from the oxygen in water molecules or other compounds in the reaction mixture.

Role of the Substrate That Acts as Oxygen Acceptor

As for the acceptor for molecular oxygen, a great variety of both organic and inorganic compounds can be oxygenated.

In general, oxygen-rich and/or hydrophilic compounds such as carbohydrates are not favorable substrates for oxygenases because these usually have many reactive groups containing oxygen, such as the hydroxyl, carbonyl, or formyl, and their biochemical function does not require further oxygenation. On the other hand, hydrophobic compounds such as lipids and aromatic compounds are often metabolized by oxygenases. These oxygen-deficient compounds generally require oxygenation in order to become biologically active or more soluble in water. By contrast, purines and pyrimidines with their hydrophilic ring systems are usually hydroxylated by the addition of water, followed by dehydrogenation.

Reaction Mechanisms and the Nature of Active Oxygen

Evidence generated from a number of laboratories has indicated that the enzyme binds oxygen only in the presence of substrate to form the ternary complex, ESO_2 , in which oxygen and substrate interact to form a product. Such a ternary complex was postulated in 1964 on the basis of binding experiments, but more direct experimental evidence was not available until 1967 when a ternary complex of tryptophan 2,3-dioxygenase-tryptophan- O_2 was demonstrated by spectrophotometric experiments. Since that time similar oxygenated intermediates have also been observed, such as those with protocatechuate 3,4-dioxygenase (an iron-sulfur protein dioxygenase), lysine monooxygenase (a flavoprotein), and cytochrome P-450. In each case, the enzyme must bind the organic substrate first, before it can be oxygenated, in contrast to oxygen-carrying pigments such as hemoglobin and hemoerythrin, which are freely and reversibly oxygenated in the absence of any effector or substrate. In fact, several lines of evidence indicate that the substrate tryptophan binds specifically to the heme coenzyme of tryptophan 2,3-dioxygenase; as a consequence, the state of the heme is altered in such a way that its reactivity toward ligands is increased by several orders of magnitude.

The nature of the so-called active form of oxygen in the above-mentioned ternary complexes has been one of the most difficult questions in this field. All oxygenase-catalyzed reactions are exothermic and are therefore irreversible. Nevertheless, molecular oxygen is a rather inert compound and at room temperature reacts slowly with the substrate compounds in the absence of enzymes. This low kinetic reactivity is usually explained on the basis that molecular oxygen is in a triplet ground state. The direct reaction of a triplet molecule with organic molecules in the singlet state is electronically spin forbidden, and therefore a substantial activation energy is required. For this reason, singlet oxygen has been suggested as a likely intermediate in many oxygenase-catalyzed reactions; however, definitive evidence is so far unavailable. It has recently been discovered that during enzymic hydroxylation of aromatic substrates, the substituent (deuterium, tritium, chlorine, bromine, etc.) displaced by the entering hydroxyl group migrates to an adjacent position in the aromatic ring. On the basis of extensive studies of this phenomenon, called the 'NIH shift', the active oxygen species involved in certain monooxygenases was postulated to be oxenoid.

On the other hand, evidence has appeared indicating that O_2^- , that is, the superoxide anion, may be the active form of

oxygen in the case of indoleamine 2,3-dioxygenase, and also in the hydroxylation reactions catalyzed by hepatic cytochrome P-450. It is, however, uncertain whether or not the superoxide anion is the general form of active oxygen in all oxygenase-catalyzed reactions or whether these enzymes represent a new class of enzyme that utilizes the superoxide anion rather than molecular oxygen as an oxygenating agent.

Biological Function of Oxygenases

Although oxidases and dehydrogenases are mainly involved in energy metabolism, namely, the generation of adenosine triphosphate, oxygenases play important roles in biosynthesis, transformation, and degradation of essential metabolites such as amino acids, lipids, sugars, porphyrins, vitamins, and hormones. They also play a crucial role in the metabolic disposal of foreign compounds such as drugs, insecticides, and carcinogens. Furthermore, they participate in the degradation of various natural and synthetic compounds by soil and airborne microorganisms in nature and are, therefore, of great significance in environmental sciences. Therefore, the significance of biological oxygen fixation in medicine, agriculture, and microbiology, and also in food technology, cosmobiology, public health problems, and biochemistry in general, has now been well established.

For example, certain oxygenases fulfill exceptionally important biological functions as exemplified by prolyl and asparaginyl hydroxylases as oxygen sensor as well as NO synthase as already mentioned. Several other examples are being briefly described.

Ribulose 1,5-bisphosphate carboxylase/oxygenase (EC 4.7.1.39), also known as 'rubisco', catalyzes the CO_2 fixation as well as dioxygenase reaction and is the most abundant naturally occurring catalyst in nature. The global fixation of O_2 by rubisco can be estimated to be $\sim 10^{11}$ metric ton (t) per year.

Tryptophan 2,3-dioxygenase (EC 1.13.11.11), also known as tryptophan pyrrolase, catalyzes the pyrrole ring cleavage by the insertion of two atoms of oxygen to produce L-formylkynurenine. This enzyme is present in the liver and is highly specific for L-tryptophan.

On the other hand, indoleamine 2,3-dioxygenase (EC 1.13.11.42), also known as IDO, shows broad substrate specificity including L- and D-tryptophan, L- and D-5-hydroxytryptophan, serotonin, and so forth and is widely distributed in almost all organs and tissues except in the liver. IDO is induced by interferon and has been implicated in the defense mechanism against infection by depleting tryptophan from the infected tissues and cells. More recently, allogenic fetal rejection was reportedly prevented by tryptophan catabolism by IDO.

The prostaglandin endoperoxide synthases I and II (COX-1 and COX-2) are the major targets of nonsteroidal anti-inflammatory drugs including aspirin, indomethacin, ibuprofen, and the new COX-2 inhibitors. These drugs reduce inflammation, pain, and fever and also fatal thrombotic events, colon cancer, and Alzheimer's disease.

Another common dioxygenase involved in lipid metabolism and widely distributed in both animals and plants is lipoxygenase (EC 1.13.11.12), which is also known as LOX,

lipoxidase, lipoperoxidase, or carotene oxidase. It is a non-heme iron-containing dioxygenase and catalyzes the formation of hydroperoxy derivative of unsaturated fatty acids. Of particular interest is the 5-LOX that catalyzes the dioxygenation of arachidonic acid to produce corresponding *cis,trans*-diene hydroperoxide followed by the dehydration to generate leukotrien A₄, another biologically important lipid mediator.

Unspecific monooxygenase is a heme-thiolate enzyme commonly known as cytochrome P-450, hepatic microsomal monooxygenase, xenobiotic monooxygenase, or aryl-4-monooxygenase (EC 1.14.14.1), and catalyzes hydroxylation of a wide variety of both aromatic and aliphatic compounds. Monooxygenases also catalyze a seemingly diverse group of reactions including epoxide formation, dealkylation, decarboxylation, deamination, and N- or S-oxide formation. Although the overall reactions catalyzed by various monooxygenases appear grossly unlike one another, the primary chemical event is identical, because these processes are all initiated by the incorporation of one atom of molecular oxygen into the substrate.

Oxygenases in Evolution

Primitive Earth is believed to have started with an oxygen-free anaerobic environment. Therefore, the minimum manifestation of life is capable of occurring in the absence of molecular oxygen, as exemplified by the strictly anaerobic microorganisms, which survive and grow solely in the absence of molecular oxygen. With the appearance of oxygen in the Earth's atmosphere, molecular oxygen became a more useful and efficient tool as the terminal electron acceptor. Oxygenases then appeared gradually with the subsequent development of extensive and complicated metabolic pathways for essential components of cell structures and of regulatory mechanisms of metabolism and growth. The appearance of aerobic form of life paved the way for oxygenase-catalyzed reactions by which complicated messengers and structural compounds

such as sterols, prostaglandins, and neurotransmitters are efficiently synthesized, while cytochrome P-450 plays an essential role in the metabolism of thousands of drugs, carcinogens, and other synthetic compounds and is probably the largest family of proteins that has been cloned and characterized to date. In an evolutionary sense, oxidases preceded oxygenases but the latter appears to be a more advanced oxygen-utilizing catalyst associated with the most advanced and highly specialized life processes.

P2Y Receptors

G R Dubyak, Case Western Reserve University, Cleveland, OH, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Agonist A molecule that binds to a receptor resulting in functional activation of the receptor.

Antagonist A molecule that binds to a receptor and keeps the receptor in a functionally inactive state.

Effector protein An intracellular protein, such as an enzyme or ion channel, whose activity is regulated by interaction with G proteins. Effector proteins regulate the production of second messenger signals.

G protein An intracellular protein that becomes active when it binds guanosine triphosphate (GTP) and becomes inactive when it hydrolyzes the bound GTP to guanosine diphosphate (GDP). G proteins act as signal transduction proteins that couple cell-surface receptors to the regulation of intracellular effector proteins.

G-protein-coupled receptor (GPCR) A cell-surface receptor protein for an extracellular signaling molecule; GPCR

reversibly interacts with G proteins to activate intracellular signal transduction pathways. There are thousands of different GPCRs that selectively bind a wide variety of extracellular signaling molecules, including many hormones and neurotransmitters.

P2Y receptors A family of related GPCR that become active when bound to extracellular nucleotides such as adenosine triphosphate (ATP), adenosine diphosphate (ADP), or uridine triphosphate (UTP).

Second messenger A small intracellular molecule that is transiently formed in response to the activation of an effector protein by a cell-surface receptor, such as a GPCR. Formation of the second messenger acts to relay the signal from the cell-surface receptor to the interior of the cell.

P2Y receptors are intrinsic plasma membrane proteins that mediate functional responses of intact cells to extracellular nucleotides, including adenosine triphosphate (ATP), adenosine diphosphate (ADP), uridine triphosphate (UTP), uridine diphosphate (UDP), and UDP-glucose. P2Y receptors belong to the superfamily of G-protein-coupled receptors (GPCRs), an exceptionally large group of structurally and functionally related gene products that play crucial roles in the transduction of signals between and among different types of cells. In response to the binding of extracellular nucleotides, P2Y receptors undergo conformational changes that facilitate their direct interaction with, and activation of, G proteins. In turn, the activated G proteins couple P2Y receptors to the regulation of enzymes and ion channels that facilitate generation of second messengers and intracellular signaling cascades used for the acute or chronic regulation of specific cellular functions. Appreciation of the physiological or pathological functions of P2Y receptors requires some understanding of the general mechanisms by which nucleotides are used as extracellular signaling molecules.

Extracellular Nucleotides as Signaling Molecules

In addition to their crucial roles in intracellular energy metabolism and nucleic acid synthesis, nucleotides, such as ATP, and

nucleosides, such as adenosine, play important roles as extracellular signaling molecules. Burnstock and his colleagues generated many of the initial hypotheses regarding the roles of purines in nonadrenergic, noncholinergic neurotransmission. They proposed that extracellular nucleotides and nucleosides are utilized for signal transduction at nerve endings in diverse tissues. Implicit in this concept of purinergic transmission or signaling was a requirement that ATP (or other nucleotides) be released and metabolized in a highly localized manner at sites of cell-to-cell communication. Given the emphasis on the role of purines in this neuronal signaling, initial characterization focused on describing the release of nucleotide/nucleosides at neuron-to-neuron synapses, neuron-to-tissue varicosities, or the immediate locale of neuroendocrine cells. Such studies verified that neurons and neuroendocrine cells can release ATP via standard mechanisms involving exocytosis of nucleotides co-packaged with biogenic amines or other neurotransmitters in specialized vesicles or granules.

However, subsequent research has resulted in the cloning and characterization of at least 15 distinct ATP/nucleotide receptor genes (including the P2Y receptors), four adenosine receptor genes, and a dozen different ecto-nucleotidase genes. Analysis of the expression of these genes revealed that most vertebrate cell types express one or more subtypes of nucleotide or nucleoside

receptor along with one or more of the ecto-enzymes used for metabolizing extracellular nucleotides. Because most cells lack direct proximity to nerve synapses or neuroendocrine cells, the identification of additional sources of extracellular nucleotides is a current area of investigation and speculation. Recent studies indicate that stressed or damaged cells in many tissues can locally release nucleotides via a variety of pathways ranging from irreversible cytolysis to nonlytic export through nucleotide-permeable channels. In turn, the released nucleotides activate autocrine or paracrine signaling cascades that permit those tissues to adapt to the particular stress or injury that precipitated release of the cellular nucleotides.

Regardless of the mechanism by which ATP or other nucleotides are released from cells, their half-life within extracellular compartments is generally brief due to rapid catabolism by ecto-nucleotidases. Some of these ecto-enzymes serially convert released nucleotide triphosphates (e.g., ATP) to their diphosphate (e.g., ADP) and monophosphate (AMP) forms. Other ecto-nucleotidases dephosphorylate the nucleotide monophosphates (e.g., AMP) to their corresponding nucleosides (e.g., adenosine). These nucleosides can be reaccumulated and reconverted to intracellular nucleotides via highly conserved nucleotide salvage pathways. In the case of adenosine, nucleosides can additionally function as agonists for G-protein-coupled nucleoside receptors that are distinct from the P2Y nucleotide receptors. Thus, the local release of ATP may initially activate ATP-selective P2Y receptor subtypes. Although this hydrolysis of ATP to ADP by ecto-ATPases would act to terminate signaling by these particular P2Y subtypes, this same extracellular metabolic reaction would result in activation of ADP-selective P2Y receptor subtypes. Further metabolism to adenosine might result to activation of G-protein-adenosine receptors in the same or adjacent cells. In these ways, ATP release in intact tissues can trigger the serial activation of multiple P2Y and adenosine receptor subtypes to generate complex patterns of positive or negative feedback among the various cell types that comprise the tissue. As a further complication, many cells export nucleotide diphosphokinases that catalyze transphosphorylation reactions between the various extracellular nucleotide tri- and diphosphates. Thus, released ATP may additionally drive the phosphorylation of ambient UDP to locally generate UTP that is a selective agonist for yet other P2Y receptor subtypes.

General Structure of the P2Y Receptors

As members of the GPCR superfamily, all P2Y receptors are intrinsic membrane proteins that consist of a single polypeptide chain with certain invariant structural domains. These include: (1) an extracellular amino terminal tail; (2) seven transmembrane-spanning segments (usually alpha helices); (3) three short extracellular loops and three variably sized intracellular loops that connect transmembrane segments; and (4) an intracellular carboxyl terminal tail. The exact protein domains of P2Y receptors that facilitate selective recognition and binding of the extracellular nucleotide agonists have not been identified as yet. Significantly, no single P2Y domain contains amino acid sequences similar to the well-defined nucleotide-binding sites of the many intracellular proteins that interact with ATP (e.g., ATPases, protein kinases, and nucleic acid polymerases).

Functional Classification of the P2Y Receptors

Genes encoding P2Y receptors have been identified in the genomes of all vertebrate species examined thus far. By contrast, no obvious P2Y receptor orthologs are apparent in the completely sequenced genomes of the insect, *Drosophila melanogaster*, or the nematode worm, *Caenorhabditis elegans*. At present, genes encoding eight distinct P2Y receptor subtypes have been characterized in a broad range of tissues and cell types from vertebrate organisms. These subtypes can be classified based either on their selective pharmacological recognition of different nucleotides or on their selective functional coupling to particular classes of heterotrimeric G proteins. [Table 1](#) summarizes both the pharmacological and functional properties of the eight P2Y receptor subtypes.

Based on their functional coupling to G proteins, effector proteins, and second messenger cascades, P2Y receptors can be broadly subdivided into three major groups. The P2Y1, P2Y2, P2Y4, and P2Y6 receptor subtypes predominantly couple to G_q -family G proteins with consequent activation of phosphatidylinositol-specific phospholipase C effector (PI-PLC) enzymes resulting in accumulation of inositol trisphosphate, diacylglycerol, Ca^{2+} as second messengers. The P2Y12, P2Y13,

Table 1 Classification of P2Y family nucleotide receptors

Receptor subtype	G protein–effector cascade	Selectivity for physiological nucleotide agonists	Tissue/cellular expression
P2Y1	$G_q \rightarrow PI-PLC$	$ADP > ATP \gg UDP, UTP$	Platelets; blood vessels, brain
P2Y2	$G_q \rightarrow PI-PLC$	$ATP = UTP \gg ADP, UDP$	Airways; exocrine glands; white blood cells; blood vessels, brain
P2Y4	$G_q \rightarrow PI-PLC$	$UTP \gg ATP, UDP, ADP$ (human) $UTP = ATP \gg UDP, ADP$ (rat, mouse)	Small intestine; inner ear
P2Y6	$G_q \rightarrow PI-PLC$	$UDP > UTP > ADP \gg ATP$	Gallbladder; airway
P2Y11	$G_q \rightarrow PI-PLC$ and $G_s \rightarrow AC$	$ADP > ATP \gg UDP, UTP$	Exocrine glands; kidney; white blood cells
P2Y12	$G_i \rightarrow AC/others$	$ADP > ATP \gg UDP, UTP$	Platelets; brain astrocytes
P2Y13	$G_i \rightarrow AC/others$	$ADP > ATP \gg UDP, UTP$	Brain astrocytes
P2Y14	$G_i \rightarrow AC/others$	$UDP-glucose \gg UTP, ATP, UDP, ADP$	White blood cell precursors; stem cells

and P2Y14 subtypes activate G_i -family G proteins. As a result, stimulation of these latter receptors most often leads to inhibition of adenylyl cyclase effector enzymes and reduced intracellular levels of cyclic AMP. However, depending on cellular background, these G_i -coupled P2Y receptor subtypes may also stimulate the activity of G-protein-regulated K^+ channels and/or inhibit activity of N-type voltage-gated Ca^{2+} channels. Finally, the P2Y11 receptor represents a subtype that can couple to both G_q - and G_s -dependent signaling pathways; the activation of G_s allows P2Y11 receptors to stimulate adenylyl cyclase effector enzymes and thereby induce accumulation of cyclic AMP. Thus, activation of the different P2Y receptor subtypes can variously trigger rapid changes in Ca^{2+} , cyclic AMP, lipid second messengers, and plasma membrane potential. In turn, these acute signals can be integrated within cell-specific transduction networks to regulate particular protein kinases, protein phosphatases, proteases, and transcription factors.

Pharmacological Classification of P2Y Receptors

P2Y receptors can also be categorized by their pharmacological selectivity for particular nucleotide agonists. The P2Y1, P2Y12, and P2Y13 exhibit very high selectivity for ADP over ATP and are virtually insensitive to nonadenine nucleotides. The P2Y2, P2Y4, and P2Y6 subtypes can be effectively activated by uridine nucleotides albeit with subtype-selective preferences. P2Y2 receptors show high affinity for UTP and ATP, but not the corresponding diphosphates. P2Y4 receptors are most potently stimulated by UTP over ATP (but this is species dependent), while P2Y6 receptors exhibit a preference for UDP. In general, P2Y11 receptors are activated by ATP or ATP, and less effectively by nonadenine nucleotides. The P2Y14 subtype, the most recently identified member of the P2Y family, exhibits a very high selectivity for sugar conjugates of UDP, such as UDP-glucose. Given the complex and overlapping affinities of the P2Y subtypes for naturally occurring nucleotides, considerable effort is being directed toward generation of synthetic nucleotide agonists and non-nucleotide antagonists that selectively target particular P2Y subtypes. Such subtype-selective reagents may have high potential utility as therapeutic agents in diseases that involve hyperfunctional or hypofunctional P2Y receptors.

Important Physiological or Pathological Functions of P2Y Receptor Subtypes

Understanding of the most important physiological roles for P2Y receptors has been limited by: (1) the relatively recent identification of most P2Y receptor subtypes (post 1995); (2) the current paucity of subtype-selective drugs; and (3) the rather broad expression of P2Y receptors in most tissue types. However, gene-targeting approaches have been recently used to generate knockout mice that lack the expression of P2Y1, P2Y2, P2Y4, P2Y6, or P2Y12 receptors. These mice (or tissues from the mice) exhibit significant deficits in several crucial biological responses.

Mice lacking either the P2Y1 or P2Y12 receptor are characterized by abnormalities in the blood clotting response (also known as hemostasis) that result in prolonged bleeding times. This reflects the synergistic roles of the P2Y1 and P2Y12

receptors in mediating the aggregation of platelets (the key blood cell type in the clotting reaction) in response to ATP/ADP released from damaged blood vessels. Because platelets also release large amounts of ATP/ADP during aggregation induced by other hemostatic factors (such as thrombin), P2Y1 and P2Y12 play additional roles in amplifying and extending overall blood clotting response. However, inappropriate platelet aggregation (thrombosis) can lead to interruption of normal blood flow (ischemia) to critical organs, such as the brain or heart, and thereby contribute to acutely life-threatening conditions, including stroke and heart attack. For this reason, drugs that specifically block or antagonize P2Y1 and/or P2Y12 receptors are currently being tested for the treatment of thrombotic diseases in humans.

Analyses of other knockout mice strains have revealed important roles for the P2Y2 receptor that are highly expressed in airway cells and the P2Y4 receptors expressed in the jejunal section of the small intestine. Multiple P2Y receptor subtypes are expressed in the epithelial cells from organs such as the airways, lungs, kidneys, and intestines. The major function of epithelial cells and tissues is to act as both a barrier and selectively permeable interface between very different biological compartments. For example, airway epithelial cells comprise an interface between the inspired air compartment (which contains microbes, small particles, and volatile compounds from the outside environment) and the blood compartment. In addition to physically blocking the entry of these airborne microbes, particles, compounds into the blood, airway epithelial cells secrete water, salt, mucus, and other protective proteins onto their extracellular surface that directly faces the inspired air compartment. While the secreted mucus solution acts to trap the microbes and particles, ciliated protrusions that extend from the epithelial cells beat in a synchronized manner to push the mucus solution – plus the entrapped microbes and particles – back to the nose and upper throat for eventual removal by sneezing or coughing. Activation, by ATP or UTP, of the P2Y2 receptors in different airway epithelial cells can coordinately regulate: (1) the secretion of the water, different salts, and mucus in sufficient amounts to generate mucus solutions with appropriate viscosity, fluidity, and composition; and (2) the frequency and direction of the ciliary beating required for the appropriate retrograde flow of the mucus back to the upper airways. In airways from the P2Y2 receptor knockout mice, these important epithelial functions are not appropriately regulated. Analysis of small intestine function in P2Y4 receptor–receptor mice has indicated a similar role for this P2Y subtype in the regulation of salt and fluid secretion by intestinal epithelial cells.

P2Y2 receptor deficiency also results in reduced clearance of apoptotic T-cell progenitors in the thymus because ATP released from the apoptotic thymocytes acts as a find-me signal for the P2Y2 receptor-dependent chemotaxis of phagocytic macrophages. The absence of P2Y6 receptors also perturbs normal macrophage function by reducing the production of inflammatory cytokines in response to endotoxin/lipopolysaccharide.

Future studies of additional organ- and tissue-specific functions in mice lacking these and other P2Y receptor subtypes will undoubtedly reveal other important *in vivo* roles for these receptors. Insights from these animal studies, coupled with the

development of subtype-selective antagonists, should facilitate delineation of how these receptors function in human physiology and pathology.

Glossary

Apoptosis Programmed cell death; an active form of cell suicide.

Cell cycle The ordered set of events by which a cell grows and divides.

Cell-cycle checkpoint Point in the cell-division cycle where progression through the cycle can be halted until

conditions are suitable for the cell to proceed to the next stage.

Oncogene A gene whose product has the ability to transform a normal cell into a cancer cell.

Tumor suppressor A gene that negatively regulates cell division and when lost allows the cell to progress through the cell cycle in an unrestricted manner.

p53 is a tumor-suppressor gene that is mutated in over half of all human cancers. The tumor-suppressive functions of p53 are dependent upon its activity as a transcription factor. This protein binds DNA in a sequence-specific manner to regulate the expression of select genes involved in a range of cellular processes including growth arrest, apoptosis, DNA repair, autophagy, senescence (irreversible growth arrest), and angiogenesis (new blood vessel formation). The p53 protein is activated in response to various cellular stresses and functions to suppress the transformation of a normal cell into a cancer cell. In addition, p63 and p73 are two transcription factors that are highly similar to p53 in both DNA sequence and protein structure. Collectively, p53, p63, and p73 are commonly referred to as the p53 family. Like p53, p63 and p73 act to regulate growth arrest and apoptosis. However, unlike p53, p63 and p73 also play important roles during early development.

Functional Domains of p53

The p53 protein was originally identified in 1979, and its name is derived from the apparent molecular weight of the protein (p53 = protein of 53 kDa). This protein consists of 393 amino acids and is divided into three functional domains: (1) an N-terminal transactivation domain; (2) a DNA-binding domain; and (3) an oligomerization domain (Figure 1(a)).

Transactivation Domain

The transactivation domain is located at the amino-terminus of the protein sequence (amino acids 1–73). Because the p53 gene contains multiple transcriptional start sites, the p53 protein can either contain the transactivation domain (denoted p53) or lack a full-length transactivation domain (Figure 1(a)). The full-length p53 protein is the primary isoform expressed in human cells, and this isoform is responsible for its tumor-suppressor function. Because they lack a full-length transactivation domain, $\Delta 40$ p53 and $\Delta 133$ p53 can inhibit the tumor-suppressor function of the full-length p53. This inhibition can occur by the $\Delta 40$ p53 and $\Delta 133$ p53 oligomerizing with full-length p53 and blocking its ability to activate transcription, or by independently binding p53 DNA response elements and

competing with full-length p53 for these gene promoters. Numerous proteins can bind the transactivation domain of p53 to regulate its function. This region is highly phosphorylated by kinases (Figure 1(b)), and this phosphorylation is important for controlling the stability and activity of p53 after various stimuli (see section Phosphorylation).

DNA-Binding Domain

The central region of the p53 protein, the DNA-binding domain (amino acids 100–293), is responsible for mediating the interaction between p53 and its respective DNA-binding sites. A majority of tumor-derived p53 mutations occur in the DNA-binding domain. The residues most commonly mutated in the DNA-binding domain either directly contact the DNA or are required for the structural integrity of the protein. Since p53 primarily functions as a transcription factor, these mutations result in a loss of function of the protein.

Oligomerization Domain

The carboxy-terminus of the p53 protein (amino acids 293–393) contains an oligomerization domain, which is required for the formation of transcriptionally active dimers and tetramers. The oligomerization domain also contains nuclear localization and export sequences that are required for transport into and out of the nucleus, respectively. The carboxy-terminus is also posttranslationally modified by multiple other proteins that regulate p53 stability and transcriptional activity (Figure 1(b)).

p53-Mediated Signaling

p53 functions as a sequence-specific transcription factor regulating select genes that are involved in numerous signaling pathways, including cell-cycle progression, apoptosis, autophagy, senescence (irreversible growth arrest), DNA repair, and angiogenesis (new blood vessel formation) (Figure 2). The p53 consensus binding site consists of two copies of the DNA sequence RRRCWWGYYY which are separated by a 0–13 base spacer region (R = A/G, W = A/T, Y = T/C). This binding site is

Figure 1 (a) Full-length p53 protein had several functional domains, including a transactivation domain, a DNA-binding domain, and an oligomerization domain. Differential RNA splicing can produce multiple protein isoforms that differ in the C-terminus of the protein. Alternative promoter usage produces p53 transcripts that differ only in the length of transactivation domain encoded. (b) p53 biochemical activities are affected by posttranslational modifications and mutations. The amino-terminus contains the transactivation domain that can be phosphorylated in response to certain types of cell damage. The central region of the protein contains the DNA-binding domain that is frequently mutated in human tumors. The oligomerization domain mediates the formation of p53 dimers and tetramers, is present at the carboxy-terminus of the protein, and can be modified posttranslationally by phosphorylation, acetylation, and ubiquitination.

Figure 2 p53 signaling pathways. p53 is activated by many cellular insults (activating stresses) that affect numerous pathways yielding various cellular outcomes. The two primary, most well-characterized outcomes of p53 activation are growth arrest and/or apoptosis (thick arrows). However, p53-regulated genes also take part in numerous other signaling pathways (thin arrows).

present in a majority of p53 target gene promoters and/or regulatory regions. The degeneracy of the consensus DNA binding site at eight of the 10 bases is thought to contribute to the selectivity of p53 toward certain genes in response to

various stresses. p53 can serve as a transcriptional activator or repressor, depending on the specific gene being regulated.

Growth Arrest and Apoptosis

Throughout life, human cells are exposed to agents that can induce DNA damage. Eukaryotic cells have evolved a series of surveillance pathways termed 'cell-cycle checkpoints' to ensure that cells copy and divide their genomes with high fidelity during each replication cycle. These checkpoint signaling pathways execute several important tasks, such as rapid induction of cell-cycle delay, activation of DNA repair, maintenance of cell-cycle arrest until repair is complete, re-initiation of cell-cycle progression after completed repair or initiation of apoptosis if the damage is irreparable. These checkpoints provide a fail-safe mechanism by which cells are repaired or eliminated before the damaged DNA is transferred to the daughter cells. Loss of normal cell-cycle checkpoint signaling is a hallmark of tumor cells, and p53 is the most frequently altered cell-cycle checkpoint signaling molecule. One of the major functions of the p53 tumor-suppressor protein is to modulate cellular responses to stress and induce cell-cycle arrest or death, as appropriate (Figure 2). Once a cell has been stressed or damaged, p53 initiates cell-cycle arrest allowing time for the damage to be repaired or for the stress to dissipate. p53 halts cell growth by selectively activating certain target genes, including p21^{Waf1/Cip1}, a protein that inhibits other proteins required for cell-cycle progression. If cell damage is extensive and cannot be repaired or the stress is prolonged, p53 will then activate genes to mediate apoptosis. p53 is responsible for both the activation of pro-apoptotic genes as well as the repression of

anti-apoptotic genes, and the array of p53-regulated genes involved in apoptosis is quite extensive. Although a given cell in the human body would not benefit from undergoing apoptosis, this process is sometimes necessary for the benefit of the whole organism to prevent the development of cancer.

Other Pathways Regulated by p53

p53 function is not limited to growth arrest and apoptosis. p53 also regulates genes involved in DNA repair, senescence, cellular migration, autophagy, and angiogenesis (Figure 2). Although the relationships between p53 and these various pathways are not completely understood, p53 controls these cellular functions through transcriptionally regulating downstream target genes. Future discoveries of novel p53 target genes and protein interactions will further elucidate the signaling networks in which p53 is involved.

p53 Regulation

p53 must act immediately after cell stress occurs and, thus, it is critical that the regulatory mechanisms for this protein are rapid. Following stress, the levels of many proteins in the cell are dictated by transcriptional regulation of the genes encoding the proteins; however, this is not the primary mechanism for p53. Instead, p53 regulation occurs predominantly at the protein level, which allows for rapid induction of p53 activity.

Activating Stresses

In a normal unstressed cell, the p53 protein is present at low levels due to the short half-life of the protein. However, p53 protein levels increase if the cell experiences a stress. There are numerous types of cellular stress and damage that can activate the p53 protein including lack of oxygen (hypoxia), elevated/lowered temperatures (heat/cold shock), DNA damage, metabolic changes, nucleotide depletion, pH changes, and oncogene activation (Figure 2). Cellular stresses trigger signaling pathways that converge on p53, resulting in stabilization and activation of the protein.

Posttranslational Modifications

Posttranslational modification events are dynamic processes that change protein stability and activity by altering protein–DNA and protein–protein interactions. Depending on the stress, p53 is posttranslationally modified with various moieties resulting in diverse effects on the protein's stability, activity, and specificity of DNA binding (Figure 1(b)).

Ubiquitination

Ubiquitination is the addition of ubiquitin molecules to lysine residues of a protein. Following ubiquitination, most proteins are targeted to the 26S proteasome for degradation. This is the mechanism used to rapidly turn over the p53 protein. The ubiquitination system involves numerous proteins, but the specificity of the system depends on the specific E3 ubiquitin ligase enzyme employed, which attaches an ubiquitin molecule to the correct substrate. The mouse double minute 2 (Mdm2) protein is the predominant E3 ligase that can

ubiquitinate p53, and is a key regulatory protein involved in controlling p53 protein levels.

Phosphorylation

Phosphorylation of proteins at serine, threonine, and/or tyrosine residues is a common regulatory mechanism in the cell. p53 is phosphorylated at select serine and threonine amino acids in the amino- and carboxy-terminal regions of the protein in response to select cellular stresses. These stresses include exposure of cells to byproducts of cellular metabolism, ultraviolet (UV) radiation, and drugs used in cancer therapy. Numerous kinases have been identified that phosphorylate p53. The specific kinase activated is dependent upon the stress, and each kinase is responsible for phosphorylating a distinct residue(s) on the protein. For example, p53 is phosphorylated on serine-15 and serine-20 after DNA damage and this modification is important for p53 activity. Phosphorylation of the p53 protein can yield numerous outcomes including protein stabilization, increased transcriptional activity, and alterations in subcellular localization.

Acetylation

Acetylation is a modification that can occur on lysine residues of a protein. Acetylation of a transcription factor can affect the protein's transcriptional activity, either positively or negatively, depending on the specific factor. In response to DNA damage, known transcriptional coactivators acetylate p53 at certain carboxy-terminal lysines, and this modification is important for the transcriptional activation of p53.

Protein–Protein Interactions

There are numerous proteins that regulate p53 through a physical interaction. Many of these proteins are involved in post-translationally modifying the protein, but there are other mechanisms of p53 protein regulation that involve protein–protein interactions. These interactions can both positively and negatively regulate p53.

Mdm2 is a protein that can bind and ubiquitinate p53, as mentioned above. This p53–Mdm2 interaction results in two outcomes. The first is that Mdm2 inhibits the transcriptional activity of p53 by binding to the amino-terminal transactivation domain of the p53 protein, blocking other interactions that are necessary for p53 activity. The second outcome is the ubiquitination of p53 by MDM2, which results in export of p53 from the nucleus and its subsequent degradation. Mdm2 is responsible for maintaining p53 at low levels in a normal unstressed cell, as well as attenuating the p53 response after stress. Interestingly, Mdm2 is a p53 transcriptional target upregulated by p53 in response to cellular insults, forming an autoregulatory negative feedback loop, which is the primary mechanism of negative regulation for p53.

Of note, viral proteins can also interact with the p53 protein to affect its activity. For instance, the human papilloma virus (HPV) type 16 and 18 E6 proteins negatively regulate p53 in a manner similar to Mdm2. The E6 protein binds to a protein complex containing p53, which leads to p53 ubiquitination and subsequent degradation. As a result, there is a significant correlation between the presence of HPV and multiple human cancers, in particular cervical, head and neck, and anal cancers.

Figure 3 The p53 family consists of p53, as well as its ‘siblings’ p63 and p73. p63 and p73 are highly similar to p53 structurally in that they both consist of a transactivation domain, a DNA-binding domain, and an oligomerization domain. In addition, p63 and p73 contain a C-terminal sterile-alpha motif (SAM) domain that is used primarily for protein–protein interactions. The amino acid identity between p53 and its family members is significant, with the highest sequence homology present in the DNA-binding domain.

In addition to protein interactions that negatively regulate p53 activity, there are interactions that have a positive impact on the protein as well. One example of this is the human p14^{ARF} protein. This protein is a tumor suppressor activated in response to oncogenic stimuli. Once activated, p14^{ARF} binds to the p53–Mdm2 complex, which disables Mdm2. This protects p53 from Mdm2-mediated degradation, resulting in p53 activation and subsequent growth suppression or apoptosis of cells that contain activated oncogenes.

p53 Family Members

p53 is a member of a newly identified family of related proteins that includes p73 and p63. p73 was discovered in 1997, with p63 quickly following in 1998. The three family members exhibit a high degree of sequence similarity and conserved structural domains (Figure 3). However, unlike p53, it appears that the functions of p73 and p63 are not entirely restricted to tumor suppression.

p63 and p73 Protein Structure

Like p53, both the *p63* and *p73* genes have two transcriptional start sites, that allow for the production of multiple proteins from a single gene that either contain (TA) or lack (ΔN) the transactivation domain at the amino terminus. Differential RNA splicing creates additional isoforms that differ at the carboxy terminus. Due to the lack of a functional transactivation domain, ΔNp63 and ΔNp73 isoforms act primarily as transcriptional repressors and can block the activity of other family members by the formation of protein–protein interactions (Figure 4).

p63 and p73 During Development

p63 and p73 each play important, yet very different, roles during development. p73 is involved in neuronal signaling, immune cell apoptosis, and inflammation. p63 is required for proper development of complex epithelial tissues, such as the epidermis, mammary tissue, and prostate and salivary glands. In addition to development, p63 also controls processes such as cellular adhesion and migration.

p63 and p73 in Cancer

Due to the presence of multiple protein isoforms, the roles of each p53 family member in cancer is complex and, often,

Figure 4 General model for the p53 family signaling in cancer. p53 and TAp73 function as tumor suppressors by activating downstream target genes that function in growth-inhibitory processes, such as cell cycle arrest and apoptosis. In some tumor cells, ΔNp63 or ΔNp73 isoforms can block the activity of p53 and TAp73 isoforms through competition for sequence-specific DNA-binding sites or by direct interaction with the protein, respectively. These antagonistic activities are hypothesized to prevent p53- and TAp73-mediated growth arrest and apoptosis, promoting ‘unchecked’ proliferation of cancer cells.

confusing. p53 acts as a tumor suppressor to block the malignant transformation of a cell, and the *p53* gene is mutated in over 50% of human tumors. TAp73 isoforms also maintain a role as tumor suppressors, due to their ability to activate a number of p53 target genes. p63, on the other hand, is often expressed as the ΔNp63 isoform and can block the ability of its other family members to act as tumor suppressors, thus giving ΔNp63 an oncogene-like activity (Figure 4).

Cancer Therapeutics Involving p53, p63, and p73

Since p53 is mutated in over 50% of all human tumors, many therapeutic strategies have been proposed to target p53 and its family signaling pathway, including: (1) transfer of normal p53 genes into mutant p53-containing cancer cells, (2) introduction of small molecules that convert mutant p53 proteins to proteins that are structurally normal in function, (3) identification of small molecules that mimic the function of p53 target genes, and (4) disruption of protein–protein interactions that negatively regulate p53 activity. In addition, small compounds that either (1) block the ability of ΔNp63 to inhibit

p53 and/or TAp73, or (2) induce the pro-apoptotic activity of TAp73 in tumors may also be successful in blocking cancer progression. One example of this is the use of rapamycin, a drug that blocks the activity of the mammalian target of rapamycin (mTOR) protein kinase. Because mTOR functions to negatively regulate the function of TAp73, compounds such as rapamycin can increase the stability and activity of p73 and activate apoptosis in human cancers. Given its important role in tumorigenesis, deciphering the function, regulation, and signaling pathways of the p53 family will continue to be a major focus of cancer-based research.

Parathyroid Hormone/Parathyroid Hormone-Related Protein Receptor

T J Gardella, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

G (guanine nucleotide-binding)-protein-coupled receptor (GPCR) An integral membrane protein characterized by seven membrane-spanning helical domains and the capacity to activate heterotrimeric G proteins in response to agonist binding.

Parathyroid hormone (PTH) An 84-amino-acid secreted polypeptide that functions as the major regulator of calcium-ion concentrations in blood and extracellular fluids; acts on bone and kidney cells.

PTH-related protein (PTHrP) A 141-amino-acid polypeptide that acts in a paracrine fashion to control development of the skeleton, heart, teeth, mammary glands, and other tissues. It is highly expressed in breast milk and is the usual mediator of hypercalcemia of malignancy.

PTH/PTHrP receptor (PPR, or PTH-1 receptor) A class 2 GPCR that mediates the actions of PTH and PTHrP. Functionally expressed in osteoblasts, renal proximal, and distal tubule cells and a variety of tissues during development.

Definition

The parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptor (PPR) is a 593-amino-acid, class 2 G-protein-coupled receptor (GPCR) that mediates the actions of PTH, a peptide hormone that functions as a major regulator of blood-ionized calcium and phosphate levels, and PTHrP, a key developmental protein. The PPR is expressed in bone osteoblasts and in renal proximal and distal tubule cells, the key target cells of PTH, and in mesenchymal cells of developing tissues (e.g., skeleton, heart, teeth, and mammary glands), the key target cells of PTHrP. The PPR interacts with the bioactive (1–34) regions of its two peptide ligands, PTH and PTHrP, via a bipartite mechanism that involves initial docking interactions to the amino-terminal extracellular domain (ECD) of the receptor, and subsequent signaling interactions to the extracellular loops (ECLs) and seven transmembrane domain helical region of the receptor. The PPR couples strongly to the G_{α_s} /adenylyl cyclase (AC)/3',5'-cyclic-adenosine monophosphate (cAMP)/protein kinase A (PKA) signaling cascade, and can also activate the $G_{\alpha_q/11}$ /phospholipase C (PLC)/inositol triphosphate (IP_3)/intracellular calcium (iCa^{2+})/PKC pathway. The PPR has also been shown to activate the $G_{\alpha_{12/13}}$ /RhoA/PLD/phosphatidic acid/PKC pathway, as well as the map kinase pathway, the latter via G-protein-dependent and G-protein-independent mechanisms. Jansen's metaphyseal chondrodysplasia and neonatal-lethal Blomstrand's chondrodysplasia are rare disorders of skeletal development and calcium-ion homeostasis that are caused by activating and inactivating mutations in the PPR gene, respectively. PTH peptides have anabolic effects on bone, and the bioactive PTH(1–34) fragment, as well as the intact PTH(1–84) peptide, are now in use to treat osteoporosis.

Background and Physiology

Molecular Cloning of the PPR

The complementary (c)DNA encoding the PTH/PTHrP receptor was first isolated in 1991. Two cell lines were the sources for the messenger RNA (mRNA) – the opossum kidney line, OK,

and the rat osteosarcoma cell line, ROS17/2.8. The coding sequence of the PPR revealed the classical seven transmembrane domain architecture of the GPCR super family (Figure 1). It was clear that the PPR was most homologous to the recently cloned receptors for secretin and calcitonin, and that together these receptors formed a distinct GPCR subgroup, termed the class 2 (or family B) GPCRs. This GPCR subgroup is comprised of 15 distinct peptide hormone receptors, and is well-conserved evolutionarily, having representatives present in the protochordate tunicate, *Ciona intestinalis*, the arthropod, *Drosophila melanogaster*, and the nematode, *Caenorhabditis elegans*. The cloned PPR expressed in COS-7 cells binds PTH and PTHrP with similar affinities, and each ligand activates the G_{α_s} /AC/cAMP/PKA and G_{α_q} /PLC/ IP_3 / iCa^{2+} -signaling pathways with similar potencies. The same receptor is, thus, thought to mediate most, if not all, of the biological actions of the two distinct peptide ligands.

Parathyroid Hormone

Discovery of PTH

PTH was identified as a key calcium-regulating hormone in the 1920s, when it was demonstrated that extracts of the parathyroid glands could modulate blood calcium levels and correct the tetany induced by parathyroid gland removal. The active hormone was purified from glands in 1959 and the complete 84-amino-acid sequence of bovine PTH was determined in 1970. In 1971, the N-terminal PTH(1–34) fragment was synthesized and shown to be equipotent to native PTH in *in vitro* and *in vivo* assay systems. Physiological studies performed during this period established that PTH is the most important regulator of ionized calcium (Ca^{2+}) in the blood and extracellular fluids, and that it acts on bone, where it stimulates Ca^{2+} release from the mineralized matrix, and kidney, where it stimulates Ca^{2+} reabsorption from the glomerular filtrate. Related studies established that the secretion of PTH from the parathyroid glands is precisely regulated in negative-feedback fashion by the extracellular Ca^{2+} concentration; thus, increases in blood Ca^{2+} result in decreased PTH secretion and decreases in blood Ca^{2+} result in increased

Figure 1 The human PTH/PTHrP receptor. Shown is a schematic of the PPR embedded in the lipid bilayer with selected features identified, including the conserved extracellular cysteines and their disulfide linkage arrangement; the glycosylated asparagines (N); Thr33 and Gln37, which contribute to PTH(15–34)-binding affinity; the probable cross-linking sites for ligand residues 13 (Arg186), 19 (Lys240), and 1 and 2 (Met425); conserved prolines (P), including Pro132, which is mutated to Leu in Blomstrand's chondrodysplasia; a putative interhelical interaction between Arg233 and Gln451; Ser370, Ile371, Leu427, Trp437, and Gln440, at which mutations alter responsiveness to position 2-modified PTH(1–34) antagonist ligands (also includes Met425); His223, Thr410, and Ile458, which are mutated in Jansen's chondrodysplasia to result in constitutive-signaling activity; Lys319 and Lys388, at which mutations impair G_q and G_s and G_q coupling, respectively; serines (S) that are phosphorylated upon agonist activation, and four C-terminal residues (Glu590–Met593) involved in NHERF binding.

secretion. This Ca^{2+} -mediated regulation of PTH secretion is determined by the actions of the calcium-sensing receptor, a class 3 GPCR expressed on the surface of parathyroid cells. The regulation is a highly sensitive process, such that blood Ca^{2+} levels are strictly maintained within the range of 1.1–1.3 mM. PTH is also a key regulator of blood phosphate, the principal Ca^{2+} counter-ion, and acts to suppress the reabsorption of phosphate in the kidney.

PTH effects in bone

In bone, the PPR is expressed by the bone-forming osteoblasts, as well as by osteocytes, the terminally differentiated stage of osteoblasts that are enclosed within the lacunae–canaliculi system of mineralized bone. Studies in osteoblasts have shown that a variety of responses to PTH, including alterations in the rates of cell proliferation, differentiation, and apoptosis, as well as changes in expression patterns for a number of genes encoding transcription factors, cytokines, and bone-matrix factors. These effects on osteoblasts can result in increased rates of bone formation. PTH, however, also induces osteoblasts to increase their expression of RANK-Ligand, a potent osteoclastogenic factor, and to decrease their expression of osteoprotegerin (OPG), a secreted RANK-L decoy receptor. The resulting increase in

the RANK-L:OPG ratio causes an increase in the differentiation of cells of the osteoclast lineage, and stimulates the bone-resorbing functions of mature osteoclasts. This indirect effect of PTH on osteoclasts, via the osteoblasts, likely contributes strongly to the calcium-releasing effects that the hormone has on bone.

By modulating the activities of both osteoblasts (directly) and osteoclast (indirectly), PTH plays a major role in the bone-remodeling process. The mechanisms that control the balance between the anabolic and catabolic effects of PTH on bone are complex and not fully understood; however, it is well documented that intermittent exposure to PTH (once-daily injection) results in net bone formation, whereas continuous exposure (infusion) results in net bone resorption. Recent data have implicated an important role for the canonical Wnt/ β -catenin-signaling pathway in mediating the bone-anabolic effects of PTH on osteoblasts. Recent data also suggest that PTH can stimulate bone formation through effects on osteocytes, in which PTH suppress the expression of the *Sost* gene, which encodes the secreted glycoprotein sclerostin, which can function as an inhibitor of the Wnt/ β -catenin-signaling pathway in osteoblasts. The sum cellular and molecular pathways that mediate the anabolic and catabolic effects of PTH

on bone are clearly complex and full understanding will require much further study. In any case, the anabolic effects that intermittent PTH can have on the skeleton are clear, and indeed were confirmed by a large clinical study completed in 2001, which showed that once-daily administration of recombinant human (rh) PTH(1–34) significantly reduces the risk of bone fracture in patients with osteoporosis. This peptide is, thus, now marketed in the U.S. by Eli Lilly Co. as *Forteo*TM and intact rhPTH(1–84) is marketed in Europe by Nycomed as *Preotact*TM, as treatments for this disease.

PTH effects in the kidney

The PPR is expressed by cells in the proximal and distal portions of the renal-convoluted tubule. In distal tubule cells, PTH stimulates the transcellular reabsorption of calcium from the urine, in part by affecting the luminal surface expression and activity of the calcium channel protein TRPV-5 (transient receptor potential vanilloid-5). In proximal tubule cells, PTH suppresses the surface expression of the type II sodium-dependent phosphate transporters, NPT2a and NPT2c, and thereby decreases the reuptake of phosphate from the tubular filtrate. Also in the proximal tubule, PTH stimulates the synthesis of 1,25-dihydroxy-vitaminD₃, via upregulation of the 25-hydroxyvitaminD₃-1- α -hydroxylase gene. The increased levels of activated vitaminD₃, in turn, promote calcium and phosphate absorption at the intestine, and also result in increased expression of the phosphate-regulating cytokine, fibroblast growth factor-23 (FGF23) in osteoblasts and osteocytes. PTH, together with vitaminD₃ and FGF23, form a central hormonal feedback axis that functions to maintain the extracellular concentrations of calcium and phosphate at the steady-state levels required for normal biological function.

PTHrP

Discovery of PTHrP

In the late 1980s, much effort was devoted to identifying the hypercalcemia-causing factor that is released by many tumors and, in 1987, the protein factor responsible, now termed PTHrP, was purified from tumor extracts and partially sequenced. This sequence data, in turn, led to the cloning of the corresponding cDNA, which revealed a protein of 141 amino acids showing clear N-terminal homology to PTH, as eight of the first 13 residues of the two proteins were identical (**Figure 2**). Although PTHrP(1–34) peptides were shown to mimic the calciotropic actions of PTH on bone and kidney cells, it seemed clear that PTHrP was not a calcium-regulating hormone, as its concentration in the normal circulation was too low (barely detectable), and its mRNA was found in a wide variety of tissues (e.g., brain, lung, heart, adrenals, spleen, liver, bladder, skin, stomach, breast, placenta, ovaries, and testes), in both adult and fetal life. These observations suggested that PTHrP acts in a paracrine manner, possibly in development.

Genetic manipulations of PTHrP in mice

The above hypotheses regarding PTHrP action were largely confirmed in 1994 when mice having homozygous deletion of the PTHrP gene were generated and found to die at birth with defects in endochondral bone formation, namely, premature mineralization and short limbs. Subsequent studies in mice determined that PTHrP also plays a role in the

Figure 2 PTH and PTHrP. Shown is an alignment of the bioactive (1–34) regions of human PTH and human PTHrP, with conserved residues in bold-faced type; the bar indicates the C-terminal amphipathic α -helical region, residues 15–34. Also shown is the X-ray crystal structure, in ribbon representation, of the PPR-ECD (green, the exon E2 region not resolved is shown as a red dash) in complex with the PTH (15–34) domain (yellow), as reported by Pioszak and Xu in 2008.

development of the mammary glands, hair follicles, and the heart. In 1996, mutant mice lacking the PPR gene were generated, and this established that the PPR mediates the developmental actions of PTHrP, as the PPR-deficient mice exhibited nearly the same perinatal lethality and developmental defects as those lacking the PTHrP gene.

PTHrP actions in the growth plate

Extensive studies on the cartilaginous growth plates of the fetal tibia and femur in mice genetically altered for PTHrP expression demonstrate that the protein acts in a paracrine fashion to control cell differentiation and proliferation programs in the developing tissue. PTHrP is expressed by cells in the periarticular region of the growth plate and acts on prehypertrophic chondrocytes of the central zone to delay their terminal differentiation into hypertrophic chondrocytes. This action of PTHrP in the growth plate is further regulated by at least several other morphogenetic proteins, including Indian hedgehog (Ihh), which is produced by the prehypertrophic chondrocytes and stimulates chondrocyte proliferation. Ihh also induces, as part of a feedback regulatory network, the expression of PTHrP by the periarticular cells. Similar paracrine actions of PTHrP on PPR-expressing cells are also likely to operate in the mesenchyme of other developing tissues (e.g., heart, mammary, and hair follicles).

Structure–Activity Relationships in PTH and PTHrP

Functional Domains of PTH(1–34) and PTHrP(1–34)

Both PTH(1–34) and PTHrP(1–34) peptides bind to and activate the PPR with affinities and potencies in the nanomolar range, and the two ligands interact with largely overlapping sites in the receptor. For both ligands, the major determinants of PPR-signaling potency reside within the N-terminal (1–14) regions, while those for binding affinity reside in the C-terminal (15–34) portions. Based on this physical separation of functional domains, N-terminally truncated analogs, such as

[Leu¹¹,DTrp¹²]PTHrP(7–34), have been developed as PTH-receptor antagonists. The PTH(15–34) fragment represents the minimum-length-binding fragment ($K_{\text{dissociation}} \sim 1 \mu\text{M}$). Within this domain, Trp-23, Leu-24, Leu-28, and Val-31 function as key determinants of binding, and form the hydrophobic face of an amphipathic α -helix. Within the N-terminal signaling domain of PTH, the highly conserved Val-2, plays a key role in PPR activation, as its deletion or replacement by bulky amino acids (e.g., Arg or Trp) confers antagonist behavior to the ligand.

Short amino-terminal fragments, such as PTH(1–14), exhibit little or no binding or signaling activity; however, N-terminal fragment analogs with multiple, affinity-enhancing amino acid substitutions, such as the conformationally constraining amino acid, α -aminoisobutyric acid (Aib) at positions 1 and 3, were developed that exhibit considerably higher potency. For example, [Aib^{1,3}, Gln¹⁰, Har¹¹, Ala¹², Trp¹⁴]PTH(1–14)NH₂ is $\sim 100\,000$ -fold more potent than native PTH(1–14) for stimulating cAMP formation in cell-based assay systems ($\text{EC}_{50}\text{s} = 2 \text{ nM}$ vs. $200 \mu\text{M}$) and is, thus, as potent as PTH(1–34). A modified PTH(1–14) analog similar to the one above was used by researchers at Bristol Meyers Squibb Co. to screen a compound library for potential PPR mimetic ligands, and in 2007 they reported the discovery of a small molecule that competitively inhibits the binding of the modified PTH(1–14) peptide. The compound likely binds within the activation pocket of the receptor and, thus, suggests the potential for conversion, via medicinal chemistry, into a potent PPR mimetic agonist, of which none, so far, has been reported.

Structural Studies of PTH Ligands

Solution-phase nuclear magnetic resonance (NMR) studies performed on PTH(1–34) analogs have suggested a bihelical conformation in which a short N-terminal helix (approximately residues 3–10) is joined via a turn or flexible linker to a longer more stable C-terminal helix. Some NMR studies have indicated that the bihelical peptide can adopt a U-shaped structure, whereas an X-ray crystal structure of PTH(1–34) reported in 2001 revealed a single, slightly bent α -helix extending from Val-2 to His-32. The bioactive conformation of either PTH or PTHrP, as found in the receptor-bound state, is currently uncertain.

Structure–Activity Relationships in the PPR

Molecular Architecture of the PPR

The amino-terminal domain

The PPR contains an amino-terminal ECD of approximately 167 amino acids, excluding the 23-amino-acid signal sequence (Figure 1). This ECD is Asn-glycosylated at four sites and contains six cysteine residues that are highly conserved among the class 2 GPCRs and are predicted to form a disulfide-bond network that stabilizes a protein fold used in common by these receptors. Present in the PPR ECD, but not any other class 2 GPCR, is a 45-amino-acid segment, Ser61–Gly105, which is encoded by a separate exon, exon 2, which can be deleted without an apparent effect on function. The X-ray

crystallographic structure of the isolated, bacterially produced PPR ECD was reported in 2008. The structure, shown in Figure 2, was obtained as a complex with the PTH(15–34) fragment. In 2009, the same group reported the structure of the ECD in complex with the PTHrP(12–34) fragment; the structure was similar, but not identical to the PTH-bound structure. The overall protein fold of the ECD consists of two layers of beta-sheet and two bracing α -helical domains. The fold is stabilized by the predicted disulfide-bond network. The tertiary structures of the ECDs of several other class 2 GPCRs, including the corticotropin-releasing factor receptor and the pituitary-AC-activating peptide receptor, have also been determined by crystallography or NMR methods, and these structures indeed confirm the use of the same tertiary fold. In the structure of the PPR ECD, the exon 2 domain was not resolved due to disorder. In both the PTH(15–34)- and PTHrP(12–36)-bound complexes, the ligand binds as an α -helix in a central groove of the ECD (Figure 2). Relative to the PTH-bound helix, the PTHrP helix bends slightly at the midpoint, such that the C-terminal segments of the two ligands form distinct sets of contacts with the receptor.

The juxtamembrane domain

The juxtamembrane (J) region of the PPR is comprised of the heptahelical bundle and the interconnecting loops. The structure of this domain is likely to bear at least some similarity to the heptahelical core regions of the class 1 GPCRs, rhodopsin and the β 2-adrenergic receptor, the only GPCRs for which X-ray crystal structures are available. Computer models of the PPR have been generated based on the rhodopsin structure, but the nearly complete lack of sequence homology between the class 1 GPCRs and the PPR limits their reliability. One structural feature predicted for the PPR J domain, and likely present in most if not all GPCRs, is a disulfide bond between ECL-1 and ECL-2 (Figure 1). Within the transmembrane helices of the PPR, there are a number of residues that are well-conserved in the class 2 GPCR family and are, thus, likely to help define the topology and functionality of the J-domain region. These include the prolines in TMs 4, 5, and 6, expected to induce kinks in the helices, and polar residues, such as Arg233 in TM2 and Gln451 in TM7, that are likely to contribute to networks of inter- and intrahelical side-chain interactions. The three intracellular loops (ICLs) of the PPR, particularly ICL2 and ICL3, play important roles in coupling to G-protein-signaling pathways.

The Ligand Interaction Mechanism in the PPR

The two-site model

The ligand-binding mechanism for the PPR has been analyzed by complementary biochemical and pharmacological approaches, including photochemical cross-linking of ligand–receptor complexes. The overall results suggest a two-site model, by which the C-terminal-binding domain of PTH(1–34) first interacts with the PPR ECD to provide initial docking energy, and then the amino-terminal domain of the ligand interacts with the PPR J domain, which, in turn, induces the conformational changes involved in receptor activation and G-protein coupling (Figure 3). As for most GPCRs, the ternary complex comprised of ligand–receptor and G protein is thought to be a high affinity, but transient state. Recent studies, however, suggest that certain ligands for the PPR, such as PTH(1–34) but

Figure 3 Ligand-binding and G-protein-coupling mechanisms for the PTH/PTHrP receptor. The ligand, PTH(1–34) or PTHrP(1–34), is shown to interact with the PPR via a bipartite mechanism in which the ligand's C-terminal portion (blue) interacts with the receptor's amino-terminal ECD (orange) to provide binding affinity, and the ligand's N-terminal portion (green) interacts with the receptor's ECLs and heptahelical portion (red) to induce receptor activation. The activated PPR can couple to multiple-signaling pathways via several different heterotrimeric G proteins. It couples most strongly, and in most cells, to $G_{\alpha s}$ to stimulate the AC/cAMP/PKA pathway. The PPR can also couple to the $G_{\alpha q}$ /PLC/ IP_3 / Ca^{2+} /PKC and $G_{\alpha 12/13}$ /RhoA/PLD/phosphatidic acid/PKC pathways, and some evidence suggests coupling to a pertussis toxin-sensitive G protein, presumably $G_{\alpha i}$, to inhibition of AC/cAMP, as well as to the activation of PLA_2 , although a cognate G protein for this latter pathway has not been identified.

not the C-terminally truncated, modified PTH(1–14) analogs mentioned above, nor PTHrP(1–36), can form a high-affinity state with the PPR, even when a G protein is not coupled to the receptor, and that this mode of stable binding can lead to prolonged signaling activities.

ECD domain interactions

The crystal structures of the PPR-ECD in complex with the PTH- or PTHrP-binding domains show that the ligand domain binds as an amphipathic α -helix and fits into a central groove of the protein fold. The hydrophobic face of the ligand helix, as formed largely by Trp-23, Leu-24, and Leu-28, makes extensive contacts with hydrophobic sites on the floor and walls of the groove. Relative to PTH, the PTHrP helix bends slightly at about position 27, such that the C-terminal portions of the two ligands diverge and make distinct sets of contacts. For both ligands, the highly conserved Arg20 side-chain fits into a pocket formed by a network of hydrophobic and polar groups, mostly near the receptor's N-terminus. Most, if not all, of the contact residues of the ligand have been shown to be important for binding by structure-activity relationship studies. The identified ECD contact site for ligand position 23, Trp in PTH and Phe in PTHrP, is also in agreement with photoaffinity cross-linking studies, which showed that a PTHrP(1–36) analogs modified at position 23 with photolabile benzoylphenylalanine (Bpa), cross-linked to the PPR segment

Thr33–Leu40, near the receptor's N-terminus (Figure 1). In the crystal structure, ligand residue 23 makes hydrophobic contacts to Leu41 of the receptor. The binding of the ligand's (15–34) domain to the ECD is likely to result in the N-terminal (1–14) domain of the ligand being positioned appropriately for binding to the receptor's membrane-embedded region.

J-domain interactions

Cross-linking studies have shown that positions 1 and 2 of bound PTH and PTHrP lie in proximity to Met425 at the extracellular end of TM6. Interestingly, the Bpa2-modified cross-linking ligand behaves as an antagonist/inverse agonist on the wild-type PPR, but the mutation of Met425→Leu causes it to behave as a partial agonist. These and related mutational data involving residues in TM5 suggest that the highly conserved Val-2 in the ligand plays a critical role in receptor activation, and does so by interacting with residues located at the extracellular ends of transmembrane domain helices five and six in the receptor.

Several other contact sites in the PPR J domain have been identified by cross-linking analyses, including Arg186 located at the border of the ECD and TM 1, which probably contacts ligand residue 13, as well as Lys240 at the extracellular of TM2, the probable contact site for ligand residue 19. The overall results suggest a possible model in which the N-terminal portion of the ligand, extending approximately from residue 1 to

19 and forming an α -helix, lies transversely along the extracellular surface of the receptor, and that key residues in the ligand helix, namely, Val-2, Ile-5, and Met-8, project into the membrane-embedded core of the receptor to induce receptor activation. Consistent with such a model, N-terminal PTH analogs that contain the enhancing modifications described above exhibit the same potency on a PPR mutant construct that lacks the ECD (PPR-delNt) as they do on the intact PPR. Although these studies suggest that the PPR ECD is not essential for receptor activation, the ECD is clearly required for achieving full potency and affinity with unmodified PTH(1–34), as this ligand is 100-fold weaker on PPR-delNt, as it is on the intact PPR.

PPR Signaling and Regulation

Conformational changes

As for all GPCRs, it is presumed that PPR activation involves movements in the TM helices and ICLs which result in increased accessibility of the receptor's cytoplasmic surface to G proteins; however, the exact conformational changes that occur are still largely undefined. A study using Zn(II)-metal-ion chelation strategies involving histidine-substituted PPR mutants suggests that TM3 and TM6 move away from each other during G_{α_s} activation. A similar TM3–TM6 movement has also been described for the β_2 -adrenergic receptor as well as for rhodopsin, suggesting similarity in the activation mechanisms used by the class 1 and class 2 GPCRs.

In 2003, a series of studies was initiated to investigate the receptor activation and binding mechanisms using optical kinetic approaches. These studies were based on Forster resonance energy transfer (FRET) methodology and utilized fluorescently modified receptors labeled with a variant of green fluorescent protein (GFP). To assess receptor activation, a cyan variant, CFP, was inserted in the receptor's third ICL, and a yellow variant, YFP, was added to the C-tail. In the basal state, these YFP and CFP groups lie in close enough proximity for a FRET response to occur, such that excitation illumination of the CFP ($\lambda \sim 430$ nm) results in increased fluorescent emission by the YFP ($\lambda \sim 530$ nm). Addition of PTH caused a decrease in the FRET signal, indicating a separation or reorientation of the YFP and CFP groups. The FRET responses were monitored in living cells and in real time, and revealed that PPR activation occurs on the time scale of ~ 1 s. Studies on the mechanisms of PTH(1–34) binding, performed using a fluorescently tagged ligand and a PPR-containing GFP in the ECD exon 2 region, revealed a two-step-binding process, for which the slower phase paralleled the time course of receptor activation. The slower phase was similarly paralleled by the FRET response observed between a YFP-tagged PTHR and CFP-tagged G protein. These studies in general suggest that a key, rate-limiting step in PPR-mediated signal transduction is the conformational change induced in the receptor as the N-terminal portion of the ligand engages the J-domain region of the receptor.

A few specific residues in the IC loops of the PPR involved in G-protein coupling have been identified by conventional mutational methods. These include Lys388 in ICL3, at which mutations impair both AC/cAMP (G_{α_s}) and PLC/IP₃ (G_{α_q}) signaling and Lys319 in ICL2, at which mutations selectively impair PLC/IP₃ (G_{α_q}) signaling. A binding site for the

G-protein β/γ subunit has also been mapped to the N-terminal proximal portion of the receptor's C-terminal tail.

The carboxyl-terminal tail

Molecular and cellular studies have shown that the PPR carboxyl-terminal tail plays a major role in signal desensitization/termination and receptor internalization. Upon agonist activation, several serines within the N-terminal-proximal portion of the tail (Figure 1) are rapidly phosphorylated, most likely by G-protein-specific receptor kinase-2. This phosphorylation promotes the binding of β -arrestin-1 and/or -2, and the internalization of the ligand–receptor complex into endosomal vesicles, most likely via a clathrin-coated pit-mediated process. At least some of the internalized PPR can recycle back to the cell membrane, presumably in a dephosphorylated, resensitized form. The PPR CT also mediates interaction with cytoskeletal scaffolding proteins, including the Na⁺/H⁺ exchanger regulatory factor (NHERF) family of proteins. The C-terminal four amino acids (Glu–Thr–Val–Met) of the receptor mediate this interaction by binding to one of the PDZ (postsynaptic density protein (PSD95), *Drosophila disc large tumor suppressor* (Dlg1), zonula occludens-1 protein (zo-1)) domains of the NHERF proteins. In some cells, the binding of NHERF proteins to the PPR has been shown to modulate the signaling pathways utilized by the receptor, resulting in increased PLC signaling and diminished AC/cAMP signaling. It also can reduce the lateral diffusion of the receptor on the cell surface, and the extent of receptor internalization following PTH activation, effects which involve linkage to the actin cytoskeletal network.

The PPR in Human Disease

Jansen's Metaphyseal Chondrodysplasia

This rare autosomal-dominant disease is characterized by hypercalcemia (reflecting the homeostatic functions of PTH in bone and kidney) and short-limbed dwarfism (reflecting the morphogenetic roles of PTHrP in the growth plates). In 1995, a mutation in the PPR gene, which changed His223 at the intracellular terminus of TM2, to Arg, was identified in an affected individual, and the mutation was shown to confer high basal cAMP-signaling activity to the receptor when analyzed in transfected COS-7 cells. Subsequently, three other activating mutations in the PPR were identified in patients with Jansen's disease, and each of these alters a residue at or near the intracellular termini of a TM helix: Thr410→Pro and Thr410→Arg in TM6 and Ile458→Arg in TM7. In transfected COS-7 cells, the N-terminally truncated antagonist, [Leu¹¹,DTrp¹²]PTHrP(5–36), behaves as an inverse agonist and, thus, suppresses constitutive cAMP signaling, on the mutant PPRs bearing the His223→Arg or Thr410→Pro mutation, whereas the [Bpa²]PTHrP(1–36) behaves as a selective inverse agonist on the His223→Arg mutant. These findings suggest a potential mode of treatment for patients with this disease.

Blomstrand's Chondrodysplasia

This rare embryonic lethal condition is characterized by a severely overcalcified fetal skeleton and short limbs. Three different PPR-inactivating mutations have been identified in this recessive disorder: a mRNA-splicing mutation that results

in an 11-amino acid deletion in TM5; a frameshift mutation in ECL2, and a missense mutation (Pro132→Leu) in the ECD. The phenotype seen in Blomstrand's chondrodysplasia mirrors that seen in mice having homozygous deletion of the PPR gene.

Conclusions

The PPR mediates the biological actions of two key proteins – PTH (calcium and phosphate homeostasis) and PTHrP (bone and tissue development). The so-called PTH-2 receptor reported by Usdin and co-workers in 1995 is 51% identity to the PPR at the amino acid level, and while it exhibits some overlap in ligand-binding pharmacology with the PPR, it likely interacts specifically with the hypothalamic peptide, TIP39. The PTH2R/TIP39 system is thought to play a neuro-endocrine role, possibly in nociception, as well as a role in spermatogenesis, rather than in PTH- or PTHrP-related biology. Genetic defects in the PTH/PTHrP/PPR system result in a number of diseases of calcium-ion homeostasis and tissue development. Further unraveling the molecular mechanisms by which the PPR interacts with PTH and PTHrP is an important goal of fundamental biological research, and could likely lead to new therapies for diseases of bone and mineral metabolism.

Glossary

NADPH Abbreviated form of nicotinamide adenine dinucleotide phosphate; the electron donor in reductive biosynthesis.

Pentose phosphate pathway Pathway by which NADPH is generated for reductive biosynthesis and ribose-5-P for nucleotide and nucleic acid formation.

Transaldolase Enzyme in the pentose phosphate pathway transferring three carbon units via the formation of a Schiff base.

Transketolase Enzyme in the pentose phosphate pathway having thiamine as cofactor and transferring two carbon units.

History

In 1931, Warburg demonstrated glucose-6-P's oxidation to 6-phosphogluconate with the formation of NADPH. In the following decade, Warburg, Lipmann, Dickens, and others found that the gluconate was decarboxylated to CO₂ and to a pentose phosphate that could then be reconverted to hexose-6-P. Details of the pathways were elucidated in the 1950s by Cohen, Racker, Horecker, and their associates. **Figure 1** shows the pentose phosphate pathway.

Reactions

Oxidative Segment

Glucose-6-P oxidation is catalyzed by glucose-6-P dehydrogenase, yielding 6-phosphogluconolactone and nicotinamide adenine dinucleotide phosphate (NADPH) (**Figure 2**). The spontaneous hydrolysis of the lactone forms 6-phosphogluconate, catalyzed by a specific lactonase. The gluconate is oxidatively decarboxylated to yield another NADPH and ribulose-5-P. The overall reaction of this segment is then $\text{glucose-6-P} \rightarrow \text{CO}_2 + 2\text{NADPH} + \text{ribulose-5-P}$.

Nonoxidative Segment

The ribulose-5-P is isomerized to ribose-5-P and also epimerized to xylulose-5-P (**Figure 3**). Transfer of the top two carbons as a unit from the xylulose-5-P to ribose-5-P, catalyzed by transketolase, yields seven-carbon-containing sedoheptulose-7-P and glyceraldehyde-3-P. Transfer of the top three carbon unit as a unit from the sedoheptulose-7-P to the glyceraldehyde-3-P, catalyzed by transaldolase, yields fructose-6-P and four-carbon-containing erythrose-4-P. Transfer of the top two carbons as a unit from another xylulose-5-P to the erythrose-4-P, again catalyzed by transketolase, yields fructose-6-P and glyceraldehyde-3-P. Thus, the overall reaction of this segment is $3 \text{ pentose-5-P} \leftrightarrow 2 \text{ fructose-6-P} + \text{glyceraldehyde-3-P}$.

Transketolase requires thiamine pyrophosphate as a cofactor. The two carbon unit is transferred via its addition to the thiamine ring of the vitamin. The mechanism is similar to that in the oxidative decarboxylation of pyruvate, catalyzed by the

thiamine pyrophosphate containing E1 subunit of the pyruvate dehydrogenase complex. In the transfer of the three carbon unit, catalyzed by transaldolase, a Schiff base is formed between the ketone group of the sedoheptulose-7-P and a lysine residue at the active site of the enzyme. The mechanism is similar to that in fructose-1,6-bisphosphatase aldolase catalysis.

Overall Balance and Carbon Fate

On balance, 3 glucose-6-P (18 carbons) are decarboxylated to yield three CO₂ and 3 pentose-5-P (15 carbons) (**Figure 4**). The rearrangements, catalyzed by transketolase and transaldolase produce 2 fructose-6-P (12 carbons) and glyceraldehyde-3-P (3 carbons). The CO₂ contains carbon 1 of the glucose-6-P (**Figure 5**). The origin of the top 3 carbons of the 2 fructose-6-P are carbons 2 and 3 of the glucose-6-P.

Mode of Operation

Shunt or Cycle

Since glucose-6-P is converted to fructose-6-P and glyceraldehyde-3-P, the pentose phosphate pathway has been viewed as an alternate route for the conversion of glucose-6-P to intermediates of the glycolytic pathway. Therefore, the pathway has also been called the hexose monophosphate shunt. Since the fructose-6-P can be isomerized to glucose-6-P that can re-enter the pentose phosphate pathway, the pathway has also been viewed as a cycle and called the pentose cycle.

Regulation

The dehydrogenation of glucose-6-P, the first step, is considered to be the rate-limiting step in the oxidative segment. Control is through the activity of glucose-6-P dehydrogenase regulated by the concentration of nicotinamide adenine dinucleotide phosphate (NADP). NADPH competes with the NADP for binding to the enzyme, thus tightly coupling NADPH production to utilization. When NADPH is utilized (e.g., in fatty acid synthesis), the NADPH is oxidized, increasing NADP and stimulating flux through the oxidative segment.

Figure 1 Depiction of the pentose phosphate pathway as a cycle composed of oxidative and nonoxidative segments.

Figure 2 Reactions of the oxidative segment of the pentose phosphate pathway.

Flux through the nonoxidative segment is determined by the concentration of pentose-5-P. The activity of the pathway is coordinated with that of the pathways utilizing its products. Recent studies identify xylulose-5-P in the pathway as mediating the effect of carbohydrate feeding on the glycolytic pathway and regulating the enzymes required for fatty acid and triglyceride synthesis.

Other Functions

The pentose phosphate pathway is the route by which pentose from food is metabolized. Erythrose-4-P in some organisms is used as an intermediate in the synthesis of the aromatic ring of the amino acids. D-Xylulose formed in the glucuronic acid pathway is further metabolized via the pentose phosphate pathway.

Quantitation

Methods

Estimates of the activity of the pathway rest on measurements of the activities of its enzymes, particularly of glucose-6-P dehydrogenase, and of concentrations of intermediates in the pathway, as well as yields of labeled products after

administering labeled substrate and intermediates of the pathway. Specifically, carbon-labeled glucoses have been used to quantitate the amount of glucose utilized by the pathway relative to other pathways utilizing glucose. The quantitations depend on (1) the fact that carbon 1 of every molecule of glucose-6-P entering the pathway is oxidized to CO₂, while via glycolysis and the tricarboxylic acid cycle, carbons 1 and 6 are oxidized to CO₂ to essentially the same extent, or (2) the randomization of carbons 2 and 3 of glucose-6-P occurring in the nonoxidative segment (Figure 5).

The amounts of glucose oxidized and that utilized by the pathway are different. Thus, while the three molecules of glucose-6-P that enter the pathway (Figure 4) are oxidized, and 2 glucose-6-P equivalents are reformed, only a net of 1 glucose-6-P is utilized. It is converted to CO₂ and glyceraldehyde-3-P. If, as can occur in the liver, 2 glyceraldehyde-3-P that are formed are converted to 1 glucose-6-P, the balance becomes 6 glucose-6-P → 12 NADPH + 6 CO₂ + 5 glucose-6-P. Hence, 6 glucose-6-P are oxidized, but only 1 glucose-6-P is utilized (completely oxidized to CO₂).

Estimates

The pathway is present in all cells. The highest activities are found in tissues where lipogenesis is prominent, for example,

Figure 3 Reactions of the nonoxidative segment of the pentose phosphate pathway.

Figure 4 Chemical balance in the reactions of the pentose phosphate pathway.

Figure 5 Fate of the carbons of the glucose-6-P (G6P) in its metabolism via the pentose phosphate pathway.

liver, mammary gland, particularly during lactation, and adipose tissue. The pathway is also active in the reproductive glands, adrenal gland, and red blood cells. In those tissues 10–20% of glucose utilization may be via the pathway. The pathway has relatively high activity in growing tissue, for example, in fetal and newborn tissues and tumors.

Clinical Importance

Maintaining the integrity of the red blood cells depends on having an adequate supply of reduced glutathione to protect the cells from toxic peroxides, as well as maintain hemoglobin

in a reduced state. Several hundred million people, mainly in Africa, Asia, and the Mediterranean, have a genetic deficiency of glucose-6-P dehydrogenase. Drugs that increase the formation of peroxide, infections, and other causes of oxidative stress can induce acute hemolysis and hence anemia in those individuals.

The Wernicke-Korsakoff syndrome is a neuropsychiatric disorder occurring in individuals with a dietary deficiency of thiamine. Findings are eyeparalysis, abnormal gait, confabulation, and loss of memory. A genetic defect in transketolase has been suggested as the reason that the syndrome is only observed in a small portion of those with thiamine deficiency. A genetic abnormality in transketolase has recently been found in a man with liver cirrhosis.

Glossary

Large dense core vesicles/secretory

granules Membrane-enclosed 300–500 nm diameter peptide-containing storage organelles formed from the *trans*-Golgi network in neuroendocrine cells.

P-type ATPase A family of pumps whose members use the energy of adenosine triphosphate (ATP) to

transport cations uphill across membranes, undergoing a cycle of phosphorylation and dephosphorylation.

Type I integral membrane protein A protein that crosses a phospholipid bilayer once, with its N-terminus projecting into the extracellular environment/lumen of the secretory pathway and a cytosolic C terminus.

Generation of a C-terminal α -amide group on a peptide occurs by hydroxylation and cleavage of a C-terminal glycine residue and is a prevalent posttranslational modification essential for the production of many of the peptides that serve as hormones and neurotransmitters. Approximately half of all bioactive peptides are α -amidated, including gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), oxytocin, vasopressin, calcitonin, gastrin, cholecystokinin (CCK), neuropeptide Y (NPY), substance P, and pituitary adenylate cyclase-activating polypeptide (PACAP). The α -amide group prevents ionization of the C terminus, which may increase receptor binding, hydrophobicity, and/or half-life. In vertebrates, C-terminal α -amidation is accomplished via the activity of peptidylglycine α -amidating monooxygenase (PAM), a bifunctional enzyme localized to large dense core vesicles in neuroendocrine tissues.

Biochemistry and Enzymology of PAM

PAM is composed of two protease-resistant catalytic cores targeted to the luminal compartment of secretory granules, peptidylglycine α -hydroxylating monooxygenase (PHM; EC 1.14.17.3) and peptidyl- α -hydroxyglycine α -amidating lyase (PAL; EC 4.3.2.5). PHM catalyzes the stereospecific α -hydroxylation of all C-terminally glycine-extended peptide substrates. PAL then catalyzes cleavage of the N–C bond of the α -hydroxyglycine, generating the α -amidated peptide product and glyoxylate (Figure 1).

PAM Structure

Bifunctional PAM is a type I integral membrane protein whose structure is highly conserved in vertebrate phylogeny. From N to C terminus, it contains a signal sequence, proregion, PHM catalytic core, noncatalytic spacer region (exon A), PAL catalytic core, transmembrane domain, and cytosolic domain. The hydrophobic signal sequence is cleaved cotranslationally in the endoplasmic reticulum; the prosequence is removed in a post-*trans*-Golgi network compartment. Tissue-specific endoproteolytic cleavage at pairs of basic amino acids can remove the proregion, separate the two catalytic domains, and release the catalytic domains from the transmembrane

domain. Poorly conserved linker regions follow both catalytic domains and are susceptible to cleavage by exogenous proteases. Additionally, alternative splicing can generate soluble, monofunctional PHM or soluble, bifunctional PAM. Soluble PAM proteins are secreted with their amidated product peptides, while integral membrane PAM proteins undergo endocytosis, guided by routing determinants and phosphorylation at multiple sites in the cytosolic domain (Figure 2).

PAM Substrates

Virtually any peptide with a C-terminal glycine residue can serve as a PAM substrate. PAM generates α -amides of all 20 amino acids. In addition, PAM catalyzes the amidation of nonpeptidergic substrates such as fatty acyl glycines, glutathione, the aspirin metabolite salicylurate, bile acid glycine conjugates, and leukotriene C₄. In addition to stereospecific α -hydroxylation of glycine-extended precursors, purified PHM can also catalyze N-dealkylation, O-dealkylation, and sulfoxidation of nonpeptidergic substrates.

Peptidylglycine α -Hydroxylating Monooxygenase

Essential cofactors

PHM requires the presence of molecular oxygen, a single electron donor (generally ascorbic acid or vitamin C), and copper.

Ascorbic acid (vitamin C)

Ascorbate is transported across the plasma membrane via a Na⁺-dependent transporter enriched in neuroendocrine tissue, SVCT2. How cytosolic ascorbate reaches the lumen of the secretory pathway is currently unclear. Nevertheless, concentrations of ascorbate are 5- to 10-fold higher in the lumen of the secretory pathway than in the cytosol. The millimolar concentrations of ascorbate in the luminal compartment ensure that luminal copper is reduced, as required for the enzymatic cleavage of molecular oxygen by PHM. In this oxidation–reduction reaction, PHM converts 2 mol of ascorbate into 2 mol of semidehydroascorbate, which disproportionate to form dehydroascorbate and ascorbate. Other single-electron reductants can substitute for ascorbate to provide reducing equivalents for Cu²⁺; consistent with this, no ascorbate-specific binding site has been identified on PHM.

Figure 1 PAM reaction and structure. (a) Bifunctional PAM-catalyzed conversion of glycine-extended precursor into hydroxyglycine intermediate and amidated product plus glyoxylate. (b) Domains of integral membrane PAM-1 with salient features: KR and KK lysine–arginine and lysine–lysine dibasic cleavage sites; H, copper-binding histidine; M, copper-binding methionine; N-CHO, N-linked glycosylation site; TMD, transmembrane domain; CD, cytosolic domain, a multiply phosphorylated unstructured domain.

Figure 2 PAM in secretory granules. Soluble and membrane PAM isoforms from rat, pond snail, and fruit fly in mature secretory granule. Alternative mRNA splicing at hot spots generates soluble PAM-3, which lacks exon A and the TMD; it is secreted with the amidated product. *Lymnaea stagnalis* membrane PAM contains four functional PHM domains and an exon A-like linker sequence. *Drosophila* PHM and PAL-1/2 are encoded on separate genes. PAL-1 is a soluble protein and may be secreted with processed peptide. PAL-2 contains a transmembrane domain and may be recycled via endocytosis to post-Golgi complex compartments. CD, cytosolic domain, a multiply phosphorylated unstructured domain.

Copper

Copper is required in trace amounts by a limited group of cuproenzymes. However, in excess, copper can support the Fenton reaction, generating reactive oxygen species, which attack cellular constituents with diffusion-limited kinetics. To avoid this problem, copper transporters and copper

chaperones deliver this critical metal to these cuproenzymes while preventing toxic intracellular actions. The transport of Cu^{1+} across the plasma membrane requires Ctr1 in mammals. Atox1, a cytosolic copper chaperone, delivers Cu^{1+} to ATP7A and ATP7B, homologous P-type ATPases that pump Cu^{1+} into the lumen of the secretory pathway, where it can be loaded onto luminal cuproproteins or excreted from the cell.

Structure and reaction mechanism PHM binds two moles of copper, each of which plays a distinct role in the α -hydroxylation reaction. Composed almost entirely of β strands, the catalytic core of PHM consists of two structurally homologous domains (Figure 3). Mutagenesis and phylogenetic comparisons identify a limited number of conserved residues. The copper-binding sites are conserved: three histidine residues in the N-terminal half of PHM bind Cu_A , also known as Cu_H , and two histidines plus one methionine residue in the C-terminal half bind Cu_B , also known as Cu_M . Although reducing equivalents donated by both Cu_A and Cu_B are essential to the reaction, the two Cu ions are separated by a 10 Å solvent-filled cleft. The glycine-extended peptide substrate binds in a conserved, hydrophobic substrate-binding pocket located near Cu_B , placing the α -carbon of the glycine adjacent to molecular oxygen bound to Cu_B , with the C terminus of the glycine residue salt bridged to a conserved arginine residue. Several hydrophobic residues near the active site are conserved, along with proline and glycine residues that define the loop regions. The molecular oxygen consumed in the reaction binds only to the enzyme/peptidylglycine complex, and it is not yet clear how electron transfer is accomplished. The reaction is tightly coupled, with little generation of reactive oxygen species, and the two copper ions do not move much closer to each other during catalysis.

Figure 3 PHM active site. The structure determined by crystallization of oxidized PHMcc with its Ac-diiodo-Tyr-Gly substrate is shown to illustrate the structural role played by the disulfide bonds. Histidine ligands to Cu_A and Cu_B are blue; the methionine ligand to Cu_B is gold; substrate-binding residues are green; the substrate is shown in ball and stick format. The disulfide bonds in PHM are numbered (except for bond 1, they are totally conserved): 1, Cys⁴⁷–Cys¹⁸⁶; 2, Cys⁸¹–Cys¹²⁶, links $\beta 3$ to the $\beta 5$ – $\beta 6$ loop; 3, Cys¹¹⁴–Cys¹³¹, links $\beta 5$ to the $\beta 6$ – $\beta 7$ loop; 4, Cys²²⁷–Cys³³⁴, links $\beta 13$ to $\beta 22$; 5, Cys²⁹³–Cys³¹⁵, links $\beta 19$ to $\beta 21$. From Prigge ST, Mains RE, Eipper BA, and Amzel LM (2000) New insights into copper monooxygenases and peptide amidation: Structure, mechanism and function. *Cell and Molecular Life Sciences* 57: 1236–1259.

Pharmacological inhibition Disulfiram, used clinically in the treatment of chronic alcoholism, inhibits PHM activity *in vivo* via its ability to chelate copper. When assayed *in vitro*, after the addition of exogenous copper, the catalytic core of rat PHM displays paradoxically enhanced activity after *in vivo* disulfiram administration. A mechanism-based inhibitor of PHM, trans-styrylacetic acid (phenylbutenoic acid), has also been identified.

Peptidyl- α -Hydroxyglycine α -Amidating Lyase

Limited trypsin digestion and analysis of peptidyl- α -hydroxyglycine α -amidating lyase (PAL) truncation mutants revealed a stable catalytic core with no subdomains. The single N-linked glycosylation site near the COOH terminus of PAL is utilized, although glycosylation is without effect on the catalytic activity of PAL. The catalytic core of PAL is a six-bladed beta-propeller. An active site Tyr sits close to a Zn ion, which is coordinated to 3 His residues. Calcium plays a structural role, and the N- and C-termini of PAL are latched together, constraining the location of PHM. No reliable mechanism-based small-molecule inhibitors of PAL have been characterized. The reaction catalyzed by PAL is most similar to the reaction catalyzed by ureidoglycolate lyase.

Evolutionary Relationships

The process of peptide amidation is highly conserved. In invertebrates such as *Drosophila melanogaster* and *Caenorhabditis elegans*, PHM and PAL are encoded by separate genes; a single PHM gene may be accompanied by more than one

PAL gene. PHM and PAL homologs are not found in the genome of *Saccharomyces cerevisiae*. Intriguingly, *Lymnaea stagnalis*, a molluskan pond snail, expresses a huge membrane PAM with four independent, catalytically active PHM domains followed by a single PAL domain. *Schistosoma mansoni*, a nematode and potent human pathogen, expresses a heavily glycosylated, soluble PHM with atypical catalytic features as well as PAL. The copper-binding ligands, substrate-binding site, disulfide bonds, and selected glycine and proline residues of PHM are conserved across species.

The cofactor requirements of PHM demonstrate homology to another copper, ascorbate and dioxygen-requiring enzyme, dopamine- β -monooxygenase (DBM; EC 1.14.17.1). DBM converts dopamine to norepinephrine in selected neurons and adrenal chromaffin cells. The catalytic core of PHM is 32% identical to a 291-amino-acid stretch in DBM. The Cu_A and Cu_B -binding motifs and disulfide-bonding patterns of PHM are conserved in DBM. *Cnidarians*, such as the sea anemone and *Hydra*, use amidated peptides, not catecholamines such as norepinephrine for neural transmission, suggesting that PHM is the more ancestral enzyme. cDNA library screening of human senescent fibroblasts revealed the presence of a third sequence with significant homology to PHM, monooxygenase X (MOX; X13255). No substrates or hydroxylated products have yet been identified for this putative monooxygenase.

PAM Expression

PAM expression is most prevalent in heart atria, the pituitary gland, and peptide-producing neurons of the central and enteric nervous systems. Nevertheless, PAM expression is widespread, as transcripts can be detected in airway and olfactory epithelia, smooth muscle cells, endothelium, brain ependymal cells, astrocytes, and fibroblasts.

During development, PAM is first detected immunohistochemically at embryonic day 9 (E9) in the putative cardiogenic region and at E13 in peptide-producing neurons. PAM is also highly expressed in limb mesoderm and mesenchyme flanking the nasal, maxillary, palatal, and dental epithelia during embryonic tissue fusion and remodeling. Most *Drosophila* PHM knockout flies die as young larvae, during the molting process, with malformation of the mouth hooks. A role for PAM in these areas during development is not yet clear.

PAM Molecular Genetics

The human PAM gene is located on chromosome 5q14-21 and the mouse *Pam* gene is on chromosome 1. The rat PAM gene contains at least 28 exons encompassing >160 kb. At least two putative promoters upstream of the translational start site and proregion in exon 2 have been identified. PHM is encoded by exons 3–14 (excluding exon 13). The alternately spliced noncatalytic region between PHM and PAL is encoded by exon 16, which is bordered by at least 40 kb of intronic sequence. PAL is encoded by exons 17–24. Most of the intron/exon junctions in rat, which preferentially produce bifunctional PAM messenger RNA (mRNA) transcripts, and

D. melanogaster, which contains separate PHM and PAL genes, are conserved. Interestingly, rat-breeding stocks vary in their alternative splicing of PAM: Harlan Sprague-Dawley rats eliminate the exon A linker in their mRNA transcripts in pituitary, while Charles River Sprague-Dawley rats retain this domain.

Dysregulated Peptide Amidation

Due to the plethora of physiological functions regulated by amidated peptides, deficits in peptide amidation have very detrimental consequences for the organism.

Overexpression of Amidated Peptides

Many amidated peptides, for example, PACAP, NPY, and gastrin-releasing peptide (GRP), serve as autocrine or paracrine growth factors. Numerous tumors of neuroendocrine origin secrete amidated peptides that serve this function, and PAM expression is concomitantly upregulated. Amidated peptides secreted by neuroendocrine tumors disrupt normal physiological function. For example, small cell lung carcinomas often secrete GRP, while amidated isoforms of parathyroid hormone related protein (PTHrP) sustain bone growth and produce the hypercalcemia of malignancy. Gastrin-secreting tumors (gastrinomas) are frequently encountered in Zollinger–Ellison syndrome, which presents clinically as peptic ulceration; vasoactive intestinal polypeptide-secreting tumors (VIPomas) of pancreatic or duodenal origin, present with voluminous watery diarrhea in Verner–Morrison syndrome. Hence, pharmacological inhibition of PAM activity may be a rational therapeutic strategy in the treatment of such amidated peptide-secreting tumors.

Impaired Peptide Amidation

Based on assays of amidated product peptides, peptide amidation is impaired in the context of dietary deficiencies of ascorbate or copper, genetic deficiencies of copper-translocating proteins, or targeted gene disruption of the PAM gene.

Impaired copper delivery

A reduction in copper delivery to the secretory pathway results in a diminished ability to produce amidated peptides. This can be the result of nutritional deficiencies of copper or ascorbate or genetic malfunctioning of copper transporters. In mammals, ATP7A receives Cu^+ from the cytosolic chaperone Atox1 and transports it into the lumen of the secretory pathway, where the catalytic cores of cuproenzymes, such as PHM, DBM, and tyrosinase, reside. Mutations in ATP7A result in the X-linked copper-deficiency disorder, Menkes disease, which presents clinically with profound neurodegeneration. The mottled brindled (Mo^{Br}) mouse, which contains a six base pair in-frame deletion in ATP7A, serves as the mouse model of Menkes disease. Although PAM protein expression is unchanged, the concentrations of amidated neuropeptides, for

example, joining peptide (JP), CCK, and PACAP, are reduced in the pituitary gland and central nervous system of afflicted males relative to age-matched wild-type mice.

Targeted gene disruption

Insertion of a P-element containing transposon within the *D. melanogaster* PHM transcriptional unit eliminated PHM expression and resulted in early larval lethality with relatively few morphological defects. PAM null mice do not survive past embryonic day 14.5, with the most noticeable defect being intractable edema. No PHM or PAL enzymatic activity is detectable in homogenates of null embryos, and heterozygotes display half the wild-type level of PHM and PAL activity in age-matched wild-type mice. Thus, PAM is the only enzyme responsible for C-terminal peptide α -amidation *in vivo*. Mice heterozygous for PAM display increased anxiety-like behavior and are unable to maintain body temperature when kept in a cold environment.

Glossary

Electrogenic Property of a transmembrane electron-transport enzyme that generates a proton-motive force (PMF).

Heme A tetrapyrrole with a coordinated iron that can mediate electron transfer when bound to proteins. In *c*-type cytochromes the heme is covalently bound to the protein.

Iron–sulfur cluster A protein cofactor that comprises of inorganic iron and sulfur, which together form a cluster that is often involved in electron transfer.

Periplasm A subcellular compartment that lies between the inner (cytoplasmic) and outer membrane of Gram-negative bacteria.

Proton-motive force A transmembrane gradient of protons ($\Delta\rho$) that has an electrical component ($\Delta\psi$) and a chemical component ($\Delta\rho H$). Its magnitude is normally given in units of millivolts and can be calculated from $\Delta\rho = \Delta\psi - 60 \Delta\rho H$.

Respiratory Electron-Transport Systems

In mammalian mitochondrial respiration, electrons flow from low-potential cytoplasmic electron donors (e.g., NADH or succinate) to the high-potential electron acceptor oxygen. The site of oxygen reduction is the *aa*₃-type cytochrome *c* oxidase that is located within the cytoplasmic membrane (Figure 1). The key postulate of P. Mitchell's chemiosmotic theory is that many energy-consuming reactions catalyzed by integral membrane proteins, such as the adenosine triphosphate synthase, are driven by the energy contained within a transmembrane-proton electrochemical gradient (proton-motive force (PMF)), which is generated by the electron-transport system. Proton translocation is achieved via membrane-associated electron-transfer proteins. Mitchell described a redox loop mechanism whereby two electrons are transferred from the positive (P, or bacterial periplasmic) side of the membrane to the negative (N, or bacterial cytoplasmic) side of the membrane. There they combine with two protons to reduce a quinone to quinol. The quinol then diffuses back across the membrane where it is reoxidized at the P face releasing protons (Figure 1(b)). This movement of negative charge from the P to the N side of the membrane, and counter-movement of protons, produces a PMF. Structure–function studies of two key integral membrane enzymes of respiration (the structurally defined cytochrome *bc*₁ complex and the *aa*₃-type cytochrome *c* oxidase) illustrate yet another three different mechanisms that couple electron transfer to PMF generation. The cytochrome *bc*₁ complex utilizes a proton-motive Q-cycle mechanism that results in a q^+/e^- ratio of 1 (Figure 1(a)). The *aa*₃-type cytochrome *c* oxidase employs two different mechanisms to build up the PMF. Reduction of oxygen at the catalytic site involves proton transfer from the cytoplasm and electron transfer from a periplasmic donor. As a consequence, these charge movements from opposite sides of the membrane give rise to a net charge separation of 1 per electron transferred, $1q^+/e^-$. In addition, it utilizes a proton-pumping mechanism that results in one positive charge being moved across the membrane for each electron ($1q^+/e^-$). Therefore, the

stoichiometry of charge movements in the oxidases adds up to $2q^+/e^-$ transferred from donor to oxygen. It is notable that neither the proton pump mechanism nor the Q-cycle mechanism of energy conservation was originally envisaged by Mitchell.

Bacterial Periplasmic Respiratory Electron-Transport Systems That Are Dependent on the Cytochrome *bc*₁ Complex

The mammalian mitochondrial-type of electron-transport system is present in many aerobic and facultative anaerobic bacteria, for example, the well-studied soil-denitrifying bacterium *Paracoccus denitrificans*. However, many bacteria additionally have alternative electron-transport systems that utilize periplasmic electron donors and acceptors. In some cases, the periplasmic oxido-reductases will integrate easily into a mitochondrial-type of electron-transport chain. For example, in *P. denitrificans* the periplasmic oxido-reductases for the reduction of nitrite or nitrous oxide, which are important reactions of denitrification in the biogeochemical nitrogen cycle, can accept electrons via the cytochrome *bc*₁ complex (Figure 2). Due to the Q-cycle mechanism of the latter enzyme, the overall electron-transport pathway from quinol to nitrite and nitrous oxide is electrogenic, although the terminal nitrite and nitrous oxide reductases themselves are not. As a consequence, the electron transport from quinol to nitrite is less coupled ($q^+/e^- = 1$) (Figure 2) than electron transfer from quinol to oxygen ($q^+/e^- = 3$) (Figure 1(a)).

Periplasmic Electron-Transport Systems That Do Not Depend on the Cytochrome *bc*₁ Complex

Many bacteria (e.g., *Escherichia coli*) do not have genes encoding a cytochrome *bc*₁ complex. Using periplasmic electron donors and acceptors independently of the cytochrome *bc*₁

Figure 1 Mechanisms of energy conservation in respiration. (a) A basic mammalian mitochondrial electron-transport chain illustrating proton pumps and Q-cycle mechanisms of energy conservation. (b) The organization of redox loops using periplasmic electron donors found in some cytochrome bc_1 complex-independent bacterial respiratory systems.

Figure 2 Cytochrome bc_1 complex-dependent periplasmic and membrane-bound oxido-reductases involved in denitrification in *Paracoccus* species. NIR, cytochrome cd_1 nitrite reductase dimer; NOR, nitric oxide reductase; NOS, nitrous oxide reductase.

complex can raise interesting questions about the bioenergetics of these systems, particularly with respect to the means by which the electron-transfer process is coupled to the generation of a transmembrane electrochemical gradient. The molecular nature of some of these coupling mechanisms has been illuminated by recent structure–function studies on key anaerobic enzymes.

Some of these transmembrane enzymes possess two heme *b* groups at opposite sides of the membrane, which allows transmembrane electron transfer from a periplasmic to a cytoplasmic side. During oxidation of their substrate, two protons are released at the periplasmic side of the membrane while two electrons move inward via the hemes *b* to the cytoplasmic side of the membrane. There they are taken up by the acceptor along with two protons from the cytoplasm. This classical Mitchellian redox loop mechanism results in a net charge separation of one per electron transferred through the enzyme from donor to acceptor molecule ($1q^+/e^-$). Both dehydrogenases, which oxidize their substrate at the periplasmic side and reduce quinone at the cytoplasmic side, and terminal oxido-reductases, which oxidize quinol at the periplasmic site and reduce the acceptor at the cytoplasmic side, may have a redox-loop-type architecture. Examples of such electrogenic dehydrogenase are the HydABC-type hydrogenase and FdhN of *E. coli*, homologs of which are present in many bacteria and archaea. An example of such an electrogenic terminal oxido-reductase is membrane-bound nitrate reductase (NarA). Periplasmic or membrane-bound enzymes that are not designed to

contribute to the generation of a PMF will dissipate the redox free energy as heat. These enzymes receive their electrons and protons required for reduction of their allocated electron acceptor at the same side of the membrane, either the periplasm (trimethylamine N-oxide reductase (TOR), dimethylsulfoxide reductase (DMS), periplasmic nitrate reductase (Nap), the cytochrome *c* nitrite reductase (Nrf)) or the cytoplasm (succinate dehydrogenase and fumarate reductase). Electron transfer in pathways that are made up of a redox-loop-type dehydrogenase or oxido-reductase along with a nonelectrogenic oxido-reductase or dehydrogenase, respectively, will yield a net proton movement of 1 from inside to outside during electron transfer from donor to terminal electron acceptor ($q^+/e^- = 1$) (Figure 3). The most efficient free-energy transducing pathway of electron transfer from donor to acceptor requires the participation of a reductase, which both have a redox-loop-type architecture (Figure 3). The FdhN to NarA respiratory chain of *E. coli* and the Hyd to NarA (electron transfer from formate or hydrogen to nitrate, $q/e^- = 2$) are the classical systems used to illustrate such an efficient proton-motive redox loop.

Formate Dehydrogenase N

Formate is an important and widespread electron donor available to bacteria in anaerobic environments. During anaerobic growth with nitrate, *E. coli* can express a membrane-bound

Figure 3 Examples of $q/e^- = 1$ and $q/e^- = 2$ redox loop mechanisms.

formate dehydrogenase (FdhN), which oxidizes formate in the periplasmic compartment and for which a high-resolution structure has been determined. The enzyme is a homo-trimer, with each monomeric unit being composed of an integral membrane di-heme cytochrome subunit (FdhI), a membrane-anchored periplasmic ferredoxin subunit (FdhH), binding four [4Fe-4S] clusters, and a periplasmic catalytic subunit (FdhG), which binds a [4Fe-4S] cluster and catalyzes formate oxidation at a Se-Mo-*bis*-guanine dinucleotide (Se-Mo-MGD) cofactor. Electrons extracted from formate at the periplasmic active site pass down a 90-Å redox ladder to a menaquinone reductase site at the cytoplasmic face of the membrane. The redox ladder consists of eight redox centers, Se-Mo-*bis*-MGD, five iron-sulfur clusters, and two hemes. Each of these is within 12 Å of its nearest neighbor, and this serves to ensure rapid electron transfer (Figure 4). In considering the whole electron-transfer ladder from the Se-Mo-*bis*-MGD to the menaquinone, a notable feature is that the intermediary electron carriers usually function as one-electron-transfer centers. However, formate oxidation and menaquinone reduction are two-electron reactions. Thus, the Se-Mo-*bis*-MGD plays a key role in gating electron transfer from formate into the redox ladder and the Q-reductase site is the key to gating the reduction of menaquinone.

Much of the FdhN redox ladder is periplasmic, being located in the extra-membranous periplasmic FdhGH subunits (Figure 4), but the two membrane-intrinsic hemes, bound within the four-helix bundle of FdhI, are critical to charge separation across the membrane. The midpoint redox potential at pH 7 of the formate/CO₂ couple is *c.* -420 mV and that of the MQH₂/MQ couple is *c.* -80 mV. This large, *c.* 340 mV, potential drop allows efficient electron transfer against a negative-inside membrane potential of *c.* 200 mV. The movement of one electron from the periplasmic (P) face to the

cytoplasmic (C) face of the membrane and uptake of one proton at the C face gives a coupling stoichiometry of $q^+/e^- = 1$ (Figure 4).

Hydrogenase

Hydrogen is another important periplasmic electron donor for bacteria in anoxic environments. The Hya and Hyb enzymes of *E. coli* catalyze anaerobic hydrogen oxidation. There are no structures for these enzymes, but they are thought to be organized in a manner similar to FdhN. They are composed of three different subunits: an integral membrane di-heme subunit in which the hemes are stacked across the membrane; a periplasmic iron-sulfur protein (anchored by a single trans-membrane helix); and a periplasmic catalytic subunit that binds a nickel-iron cofactor at the active side. The bioenergetics of periplasmic hydrogen oxidation are thus predicted to be very similar to that described for formate, with electrons extracted for hydrogen in the periplasm passing through a multi-cofactor redox ladder and combining with protons to reduce quinone at the cytoplasmic face, thus giving $q^+/e^- = 1$.

Nitrate Reductase A

In *E. coli*, nitrate reductase A can serve as a second proton-motive arm in electron transfer from the periplasmic active site of FdhN or Hya (Figure 4). NarA is a three-subunit enzyme composed of NarGHI. NarG contains the *bis*-MGD molybdopterin cofactor at its catalytic site and a [4Fe-4S] cluster. NarH contains four additional iron-sulfur centers (one [3Fe-4S] and three [4Fe-4S]). NarGH are located in the cytoplasm and associate with NarI, an integral membrane protein of five transmembrane helices with the N-terminus and two

Figure 4 The organization of redox ladders involved in periplasmic formate-dependent nitrate reduction in *E. coli*. FdhN, formate dehydrogenase N; NarA, membrane-bound nitrate reductase A; Nap, periplasmic nitrate reductase.

inter-helix loops facing the periplasm. This subunit carries two hemes *b* stacked across the membrane. Oxidation of quinol occurs at the periplasmic side of NarI where the protons are released and the two electrons are moved from the outside low-potential heme *b* to the inside high-potential heme *b*. This charge separation makes the enzyme electrogenic, in that it contributes to the generation of a proton electrochemical gradient across the membrane (two charge separations during transfer of two electrons to nitrate; $q^+/e^- = 1$). Nar is organized in a manner very similar to FdhN, especially with respect to the equivalent FeS-containing NarH and FdhH subunits and Mo-*bis*-MGD NarG and FDHG catalytic subunits). However, the topology of the two systems is opposite (Figure 4), but the redox ladder arrangement of redox centers apparent in FdhN is also present in NarA. The midpoint redox potentials of individual cofactors in this ladder have been determined and suggest that both NarG and FdhN are part of a growing number of electron-transfer complexes in bacteria that contain a mixture of endergonic and exergonic electron-transfer steps. As in FdhN, the potential difference of *c.* 480 mV between the MQH₂/MQ and nitrate/nitrite redox couples is sufficient to drive electron transfer across the membrane against the negative-inside PMF (Figure 4).

Nonproton Motive Cytochrome *bc*₁ Complex-Independent Periplasmic Electron Transfer

In the FdhN–NarA electron-transport system, both the quinone-reducing and quinol-oxidizing arms of the electron-transport chain are proton motive and, when operating together, they yield $q/e^- = 2$. However, in principle, only one arm needs to be proton motive in order for a net PMF $q^+/e^- = 1$ to be generated. Examples of this can be seen in a periplasmic formate–nitrate electron-transport system in which nitrate is reduced by the Nap rather than NarA (Figure 3). Such a system operates under nitrate-limited growth conditions in *E. coli*.

The Nap

Nap is widespread in many species of denitrifying and non-denitrifying proteobacteria, including both *P. denitrificans* and *E. coli*. Nap is normally found as part of a three-subunit

electron-transfer system composed of NapABC. NapA is a periplasmic catalytic subunit with a [4Fe–4S] cluster and a *bis*-MGD cofactor. The crystal structure of *Desulfovibrio desulfuricans* NapA reveals that the overall organization is similar to that of the catalytic subunits of the Mo-*bis*-MGD formate dehydrogenases. NapB is a periplasmic di-heme cytochrome *c*, with both hemes having *bis*-histidinyl ligation. NapC has a single N-terminal transmembrane helix that anchors a globular periplasmic domain with four *c*-type hemes to the periplasmic surface of the cytoplasmic membrane (Figure 4). All four hemes have relatively low midpoint redox potentials (in the region of 0 to –250 mV) and have *bis*-histidinyl axial ligation.

NapC may be made up of two subdomains, each containing a di-heme pair, and it belongs to a large family of bacterial tetra-heme and penta-heme cytochromes. These cytochromes have been proposed to participate in electron transfer between the quinol/quinone pool and periplasmic redox enzymes such as the TOR, DMS, fumarate reductase, nitrite reductases, and hydroxylamine oxido-reductase. For an electron-transport pathway from quinol to nitrate through Nap, the enzyme receives electrons from membrane-embedded quinols, which are donated to the tetra-heme periplasmic domain of NapC. From there they flow via the hemes in NapB and the [4Fe–4S] cluster in NapA to the *bis*-MGD-containing catalytic site of NapA where the two-electron reduction of nitrate to nitrite is catalyzed. As discussed above for NarA and FdhN, this electron-transfer system also contains a mixture of endergonic and exergonic electron-transfer steps but it is expected that none of the eight redox centers involved will be more than 14 Å apart, thus ensuring rapid electron transfer. However, electron transfer from quinol to nitrate via Nap is nonelectrogenic ($q^+/e^- = 0$) since both the electrons and the protons required for the reduction of nitrate to nitrite are taken up at the same side of the periplasmic face of the membrane.

Multiheme *c*-Type Cytochromes and Periplasmic Electron Transfer

Multiheme *c*-Type Cytochromes

In *E. coli* three other illustrative examples of nonelectrogenic, quinol-oxidizing periplasmic electron-transport systems that

Figure 5 The organization of some nonelectrogenic periplasmic electron-transport systems in *E. coli*. Nrf, cytochrome *c* nitrite reductase; TOR, trimethylamine-N-oxide reductase; DMS, dimethylsulfoxide reductase.

include extended redox ladders are illustrated in Figure 5. The Nrf is a four-subunit electron-transport system that involves 14 redox centers (10 *c*-type hemes and four [4Fe–4S] clusters). The TOR is a two-subunit system comprising six redox centers (Mo–bis-MGD and five *c*-type hemes). Finally, the DMS is a three-subunit system containing an integral membrane subunit that is not involved in charge separation, and two periplasmic subunits that bind five redox centers (Mo–bis-MGD and four [4Fe–4S] clusters). Consideration of the Nap, Nrf, and TOR systems has revealed the participation of di-, tetra-, and penta-heme cytochromes in electron transfer. In mammalian mitochondria, the P-facing cytochrome *c* involved in electron transfer is a small mono-heme protein. However, multiheme cytochromes are a common feature of bacterial periplasmic electron transport. Other examples not mentioned so far include: (1) the octa-heme hydroxylamine oxido-reductase of nitrifying bacteria (e.g., *Nitrosomonas europaea*) and tetra-heme cytochrome *c*554, which, together with a tetra-heme NapC homolog CycB, mediate nonelectrogenic electron transfer from hydroxylamine to quinone; (2) the tetra-heme fumarate reductase of *Shewanella* species that, together with the NapC homolog CymA, reduces fumarate to succinate using electrons drawn from the quinol pool. Structural analysis of these cytochromes and other multiheme cytochromes such as the penta-heme NrfA reveals that the hemes are closely packed together to allow rapid electron transfer and are frequently arranged in pairs in which the porphyrin planes are nearly parallel or nearly perpendicular.

Iron (III) Respiration and Intermembrane Periplasmic Electron Transport

Bacterial iron respiration is the process in which the Fe(III) acts as the terminal electron acceptor in an energy-conserving bacterial respiratory electron-transport chain. It is an anaerobic process that provides a bacterium with a means of respiration when oxygen is absent and is distinct from the process of iron assimilation, in which iron is taken up into the cell by energy-consuming systems and incorporated into cell biomass. Although not a property of *E. coli*, the capacity for Fe(III) respiration is phylogenetically widespread and the ecological impact in microoxic and anoxic soils and sediments is considerable. A particular problem for Gram-negative bacteria is that at neutral pH the speciation of Fe(III) is complex as the cation is present either as insoluble polynuclear oxo/hydroxo-bridged complexes or as soluble organic chelates. Thus, Fe(III) is frequently presented to bacteria in a range of insoluble forms. The best-characterized group of Fe(III)-respiring bacteria are species of the genus *Shewanella*, which are widespread facultative anaerobes of the gamma proteobacterium group. *Shewanella* species can synthesize a number of periplasmic terminal respiratory reductases, including nitrate, nitrite, fumarate, and TORs. During growth under iron-respiring conditions, *de novo* synthesis of a number of multiheme *c*-type cytochromes that may play a role in the Fe(III) respiration process occurs and a number of genetic loci that encode multiheme cytochromes have been implicated as being important for Fe(III) respiration. Critically, these include an inner membrane tetra-heme cytochrome CymA (a NapC homolog), a small periplasmic 10-kDa tetra-heme cytochrome (STC); periplasmic deca-heme

cytochromes (e.g., MtrA); and outer-membrane cytochromes with deca-heme domains on the cell surface. The different cellular locations of these multiheme cytochromes is critical to the transfer of electrons from the inner membrane across the periplasm to the outside of the outer-membrane where direct reduction of the insoluble extracellular substrate can occur. The multiheme nature of the cytochromes may allow the proteins to form a multi-redox-centered electron wire that will be even longer than the redox ladders discussed for FdhN. Similar systems may also operate during the respiration of other insoluble respiratory substrates, such as manganese.

Synthesis of Periplasmic Electron-Transport Systems

The periplasmic location of the cofactor-containing periplasmic electron-transfer proteins raises the question as to how the organism assembles these proteins. This question is particularly relevant to a large protein complex with multiple redox centers, such as FdhN. In the case of periplasmic cytochromes *c*, the protein is translocated in an unfolded state via the Sec pathway and heme is covalently attached using periplasmic or membrane-associated assembly proteins. However, many other classes of periplasmic redox protein possess a signal sequence, processed from the mature enzyme, that includes a twin arginine motif. This motif directs the protein to the twin arginine translocase (Tat), which transports prefolded proteins with assembled redox cofactors. Some Tat substrates, including FdhGH, are very large and consequently the pore of the Tat apparatus must be ~100 Å in diameter to accommodate the largest substrates. The structure of the Tat complex is not yet known but there must be a gating mechanism, which maintains an ionic seal upon transport of these large substrates. The translocation process is also energy-driven, consuming PMF. This illustrates how the overall consideration of the biochemistry and energetics of a periplasmic electron-transfer system must take into account not only the operation of the system but also its biogenesis.

Glossary

Glutathione (GSH) A tripeptide

(γ -glutamylcysteinylglycine) found in high concentrations in cells. It is involved in redox processes, being reversibly transformed to the corresponding disulfide (GSSG).

Oxidases Enzymes able to oxidize various substrates using molecular oxygen.

Oxidative stress Condition dependent on an imbalance between reactive oxygen species (ROS) production and the capacity of cells to detoxify them readily using their enzymatic (superoxide dismutase, catalase, and various

peroxidases) and nonenzymatic defenses (vitamin E and other antioxidants).

Peroxidases Enzymes which reduce hydrogen peroxide to water, or other hydroperoxides to the corresponding alcohols. They can also use hydrogen peroxide to oxidize substrates of various kinds.

Reactive oxygen species Some are free radicals. They include superoxide anion ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), singlet oxygen (O_2^*), and hydroxyl radical ($\bullet OH$).

Redox signaling Cell signaling mediated by oxidation/reduction processes.

Cellular Respiration and Production of Reactive Oxygen Species

Cellular respiration sustains aerobic life and involves the oxidation of nutrients, with the final production of carbon dioxide and water. During this process, oxidation energy is captured in the form of adenosine triphosphate (ATP) molecules. Most of the oxygen is reduced to water by cytochrome *c* oxidase in a four-electron process. However, a small percentage of oxygen (1–3%) can be converted to the superoxide anion ($O_2^{\bullet-}$) in a mono-electronic process (Figure 1), depending on the leak of single electrons, mostly released by the mitochondrial and microsomal electron transport chains. However, several other sources of superoxide anion are also active in the cell. Superoxide undergoes dismutation to hydrogen peroxide (H_2O_2), either spontaneously or in a superoxide dismutase-catalyzed reaction. In the presence of transition metals such as iron or copper, the formation of the strong oxidizing hydroxyl radical ($\bullet OH$) is favored (Figure 1). Superoxide anion, hydrogen peroxide, and hydroxyl radical are collectively called reactive oxygen species (ROS) and considered the main agents responsible for oxidative stress. Hydrogen peroxide is a relatively stable oxidant and, when its concentration in cells increases, it must be controlled by several enzymes, in particular, catalase and the peroxidases dependent on glutathione or thioredoxin (Trx). However, several peroxidases use H_2O_2 for defensive or biosynthetic purposes. Lastly, it is increasingly recognized that H_2O_2 should be included among the cell-signaling molecules such as nitric oxide, calcium, and cyclic adenosine monophosphate (cAMP). Hence, peroxidases, enzymes capable of breaking down H_2O_2 to H_2O , act as modulators of the level of hydrogen peroxide, controlling its function as a second messenger.

Classification, Distribution, Reaction Mechanism, and Physiological Role of Peroxidases

Hydrogen peroxide, generated either by dismutation of the superoxide anion or by the action of several oxidases, is

reduced to water by a large number of enzymes including catalase and peroxidases. The latter also act on several organic hydroperoxides which are reduced to their corresponding alcohols. Peroxidases are distinguished according to their active site cofactor, which may be a heme (heme peroxidases) or a redox-active cysteine or selenocysteine residue (nonheme peroxidases).

Heme Peroxidases

Heme peroxidases are characterized by the presence of a heme cofactor at their active site. Catalase is the best-known member of the hydrogen peroxide-decomposing heme enzymes, being found in all aerobic organisms and almost exclusively located in the peroxisomes. Animal catalase is a four-subunit enzyme, each of which has a Fe(III)-heme, which is oxidized in its catalytic cycle (Figure 2). Catalase decomposes hydrogen peroxide at the highest turnover rate known, acting on two molecules of hydrogen peroxide according to the reaction

Therefore, catalase is a special case of peroxidase, in which the reductant is a second molecule of hydrogen peroxide and the overall process is a dismutation reaction. Heme peroxidases constitute a very large group of peroxidases, which are divided into two superfamilies. The first includes plant, fungal, and bacterial peroxidases, further subdivided into three classes (I to III) according to distribution and amino acid sequence homologies. The second superfamily comprises mammalian peroxidases, including myeloperoxidase (MPO), lactoperoxidase (LPO), eosinophil peroxidase (EPO), and thyroid peroxidase (TPO). Although heme is noncovalently bound in plant and fungal peroxidases, in mammalian peroxidases heme is covalently linked to the protein.

The reaction mechanism of heme peroxidases proceeds by a two-electron oxidation reaction involving electron donor substrates (AH_2 or X^-) according to the general reactions

Figure 1 Reduction of oxygen and formation of oxygen-free radicals. Oxygen is largely reduced to water by the cytochrome oxidase complex, with the concomitant generation of energy in the form of ATP (left). However, a little oxygen can be reduced univalently, with the formation of reduced intermediates (right). The first reduction product is superoxide anion ($\text{O}_2^{\bullet-}$). Hydrogen peroxide is the two-electron reduced form of oxygen. In the presence of reduced iron ions, hydrogen peroxide undergoes the Fenton reaction ($\text{H}_2\text{O}_2 + \text{Fe(II)} \rightarrow \text{Fe(III)} + \text{OH}^- + \bullet\text{OH}$), leading to the formation of the highly oxidant hydroxyl radical ($\bullet\text{OH}$). Lastly, hydroxyl radical can be reduced to water. Other metals, particularly copper, can catalyze the formation of $\bullet\text{OH}$ from H_2O_2 .

Figure 2 Catalytic mechanism of heme peroxidases. The first step is oxidation of Fe(III) in the active site of peroxidase at the resting state to compound I. Fe(IV)=O and $\text{Porphyrin}^{\bullet+}$ denote oxoferryl species and the porphyrin radical cation, respectively. In pathway (a), the electron donor substrate, generically indicated as AH_2 , transfers electrons in a two-step process, forming $\bullet\text{AH}$ radicals at each step. In the first step, compound II forms. The two radicals generated after oxidation of the substrate can dismutate or polymerize. Peroxidases use several substrates such as phenolics, thiols, reduced pyridine nucleotides, and several other chemically unrelated substances. Purified peroxidases are also able, in the presence of hydrogen peroxide, to oxidize many synthetic organic molecules. This pathway is observed in several plant peroxidases, e.g., horseradish peroxidase and ascorbate peroxidase. In pathway (b), electron-donor substrates (X^-) transfer two electrons to compound I, restoring the enzyme to its Fe(III) resting state. This occurs with halides ($\text{X}^- = \text{Cl}^-, \text{Br}^-, \text{I}^-$) and thiocyanate ($\text{X}^- = \text{SCN}^-$), which are transformed to hypohalous acids (HOCl , HOBr , and HOI) and hypothiocyanite (OSCN^-), respectively. Several animal peroxidases (myeloperoxidases, eosinophil peroxidases, lactoperoxidase, and thyroid peroxidase) follow this mechanism. In the case of catalase, hydrogen peroxide reduces compound I to the resting state Fe(III).

or

Substrates AH_2 or X^- are oxidized at the end of the reaction (A or HOX).

The reaction mechanism of catalase and peroxidases is a step process, as recognized by changes in electronic spectra. In the resting state, heme peroxidases contain a Fe(III) in their active site. Upon interaction with hydrogen peroxide, which removes two electrons, an oxoferryl porphyrin cation radical ($\text{Fe(IV)=O} \cdots \text{Porphyrin}^{\bullet+}$), called compound I, is formed. The oxidizing capacity of compound I resides on the oxoferryl

moiety and the one-electron oxidized heme radical cation ($\text{Por}^{\bullet+}$) (Figure 2). In some peroxidases, the electron can be transferred from amino acid residues such as tyrosine or tryptophan instead of porphyrin, resulting in amino acid radicals. Once formed, compound I can oxidize a reducing donor in a two-step or a single process (Figure 2). The first leads to compound II, in which the heme iron is still in oxoferryl form, but in which the porphyrin radical cation has been reduced by a substrate (AH_2). In turn, the substrate is oxidized to a free radical form ($\text{AH}^\bullet$). In the second step, compound II reacts with another molecule of the hydrogen donor (AH_2), forming the resting Fe(III) intermediate and then another substrate-free radical ($\text{AH}^\bullet$). The two substrate radicals may undergo different reactions, including a dismutation reaction [reaction 2b]. The type of reaction mechanism described occurs in several plant peroxidases such as horseradish peroxidase and ascorbate peroxidase. However, heme peroxidases can also catalyze direct two-electron oxidation of substrates, such as halides and thiocyanate, to the corresponding hypohalogenous acids and hypothiocyanite, respectively (Figure 2). This occurs in mammalian peroxidases such as MPO, LPO, and EPO. For instance, in MPO, the interaction of compound I with the largely available Cl^- forms the oxidizing species HOCl and restores the peroxidase to the resting state. In this case, only compound I is needed as an intermediate in the catalytic process (Figure 2), which occurs according to the following reaction:

MPO can also oxidize I^- which, however, is less concentrated than Cl^- in biological fluids. Although it can also oxidize Br^- , this reaction is probably not relevant *in vivo*. Hydrogen peroxide can further convert compound I to compound II, but the latter is inefficient in oxidizing chloride. In catalase, one molecule of hydrogen peroxide oxidizes the catalytic center to compound I, whereas the second molecule reduces the enzyme back to its resting state. Hydrogen peroxide therefore acts as both a reducing and an oxidizing agent.

Plant peroxidases oxidize phenolic compounds, lignin precursors, and other metabolites in order to accomplish a wide range of physiological processes, including defense against pathogens, lignin formation, cross-linking of cell-wall components, and metabolism of auxin.

Specialized functions have been described for some animal tissue peroxidases. MPO, LPO, and EPO take part in unspecific immune defense; TPO acts in thyroid hormone biosynthesis. They are all able to catalyze the oxidation of halogens to form specific products of significant biological interest. MPO is present in neutrophils and monocytes and is stored in cytoplasmic granules. The latter fuse with the phagocytic vacuole and deliver the enzyme, which generates the highly reactive hypochlorous acid, easily contributing toward destroying pathogens. EPO is released by eosinophils, which represent substantial protection against parasites. EPO uses a catalytic mechanism similar to that of MPO, but prefers bromide (Br^-) instead of chloride. LPO is released from glands, and is found in milk, saliva, the mucus of the respiratory tract and tears, and provides a barrier against pathogenic microorganisms entering the body. LPO chiefly oxidizes thiocyanate (SCN^-), found in milk and saliva, to hypothiocyanite (OSCN^-), which is toxic to many bacteria.

TPO plays a crucial role in thyroid hormone biosynthesis. This peroxidase catalyzes the oxidation of the iodide ion (I^-) to a species (probably I^+) capable of iodinating tyrosines in a two-electron process. However, TPO can also catalyze the formation of iodotyrosyl radicals in one-electron oxidation of iodotyrosines.

Nonheme Peroxidases

The nonheme peroxidases include glutathione peroxidases and peroxiredoxins, the final links connecting the hexose monophosphate pathway to hydrogen peroxide removal.

Glutathione peroxidase reduces hydrogen peroxide, fatty acid hydroperoxides, and synthetic hydroperoxides, with the concomitant oxidation of glutathione (GSH) to the corresponding disulfide (GSSG) according to the reactions

Several isoforms of the glutathione peroxidase family have been described. Five contain selenium at their active site, that is, GPx1–GPx4 and GPx6. The latter is found as a selenoprotein in humans and a cysteine enzyme homolog in rodents. The reaction mechanism of selenium glutathione peroxidases involves oxidation of the selenol ($-\text{SeH}$), in the active site, to a selenenic acid ($-\text{SeOH}$) (Figure 3). This reaction is facilitated by the easy deprotonation of selenocysteine at physiological pH (the pK_a of selenocysteine is about 5.2). Selenol is therefore present in the ionized form ($-\text{Se}^-$), which readily reacts with hydrogen peroxide and other hydroperoxides. In the second step, one molecule of reduced glutathione reacts with selenenic acid, forming a mixed disulfide (Enzyme-Se-SG). This species is then reduced by a second molecule of GSH which completes the redox catalytic cycle, restoring the active site selenol (Figure 3).

GPx1–3 are tetramers, and each monomer contains a selenium atom at the active site. Instead, GPx4 is a monomer and therefore contains only one selenium atom. GPx1 is the classic glutathione peroxidase and is essentially dedicated to general protection against oxidative stress. In fact, in comparison with normal mice, mice lacking GPx1 are more sensitive to toxins which increase oxidative stress. In the cell, GPx1 is located in both cytosol and mitochondria. GPx2 (intestinal glutathione peroxidase) is primarily expressed in the gastrointestinal tract, but may also be found in the liver. It plays a protective role in the removal of peroxides in ingested food or generated in the intestine. GPx3 is a glycoprotein mostly expressed in the proximal tubule of the kidney. It is found, as an extracellular enzyme, in blood plasma (plasma glutathione peroxidase), the aqueous humor of the eye, amniotic fluid, and lung lining fluid. GPx4 has the distinctive capacity to reduce esterified fatty acid hydroperoxides such as oxidized phospholipids of biological membranes and lipoproteins and is therefore also called ‘phospholipid hydroperoxide glutathione peroxidase’ (PHGPx). GPx4 is highly expressed in the testis, where it is involved in sperm maturation, acting as a catalyst in the oxidation of protein thiol groups in the head of the sperm. GPx5 is a Se-independent glutathione peroxidase present in epididymis. In GPx5, selenocysteine is substituted by a cysteine. The expression of GPx6 is restricted to the olfactory epithelium.

Figure 3 Comparison of catalytic mechanisms of glutathione peroxidases and peroxiredoxins GPx-SeH denotes glutathione peroxidase with its selenol group in the active site. Prx-SH represents peroxiredoxin with the peroxidatic cysteine (see text). Prx'-SH indicates another subunit of peroxiredoxin or another portion of the same subunit containing the resolving cysteine (see text). Hydrogen peroxide interacts with a selenol in the active site of glutathione peroxidase or with a reactive sulfhydryl in the active site of peroxiredoxin, forming a selenenic acid and a sulfenic acid, respectively. Selenenic and sulfenic acids react with another thiol group, forming a selenylsulfide and a disulfide, respectively, which may be further reduced by glutathione or thioredoxin, restoring the resting form of the two enzymes. Sulfenic acid in peroxiredoxin may be further overoxidized to sulfinic acid.

Peroxiredoxins are a family of peroxidases able to reduce hydrogen peroxide and other hydroperoxides in a reaction mostly coupled with the oxidation of Trx, according to the following reactions:

Trx(SH)₂ and Trx(SS) denote reduced and oxidized Trx, respectively.

In general, the donor-reducing substrate is Trx, but other substrates such as glutaredoxin and glutathione may also be involved. Mammalian cells express at least six isoforms of peroxiredoxins. Prx1, -2, and -6 are found in the cytosol, whereas Prx3 is typical of mitochondria. Prx5 is expressed in peroxisomes and endoplasmic reticulum, but also in mitochondria. According to the number and position of cysteine residues involved in the catalytic cycle, peroxiredoxins are organized into three subgroups, called typical 2-Cys peroxiredoxins (Prx1–4), atypical 2-Cys peroxiredoxin (Prx5), and 1-Cys peroxiredoxin (Prx6). All peroxiredoxins exhibit a similar basic cyclic catalytic mechanism, which essentially reproduces that shown for glutathione peroxidases (Figure 3). A major difference is that a cysteine, instead of selenocysteine, is the catalytic residue (Figure 3).

Prx1–5 need two cysteines for their catalytic cycle, a peroxidatic cysteine (C_P-SH) which reacts with hydrogen peroxide or

organic hydroperoxides and forms a sulfenic acid (C_P-SOH), and a resolving cysteine which forms a disulfide after reaction with the sulfenic moiety. In Prx5 (atypical Prx), the peroxidatic and resolving cysteines are located in the same molecule, whereas in Prx1–4 (typical Prx), each of the two catalytic cysteines is located in adjacent subunits. In the final step, Prxs are restored to their initial reduced state by hydrogen donors such as Trx. Peroxiredoxin 6 contains only the peroxidatic cysteine and, as resolving cysteine, uses one of other proteins or small molecules such as glutathione. The reactivity of the peroxidatic cysteine of peroxiredoxins is facilitated by the presence of positively charged groups which help to dissociate the thiol group, therefore forming a thiolate able to react with hydrogen peroxide. However, in addition to the low pK_a of the cysteine reacting with hydrogen peroxide, stabilization of the transition-state intermediate by a proper environment is also required. Although the reaction constants of peroxiredoxin with hydroperoxides are lower than those of glutathione peroxidases and catalase, their very high cellular abundance compensates for their lower catalytic efficiency.

At relatively high hydrogen peroxide concentrations, eukaryotic peroxiredoxins are distinctively subjected to overoxidation of their peroxidatic cysteine. In this process, the sulfenic moiety is oxidized to a sulfinic group and the enzyme is inactivated (Figure 3). It has been suggested that this inactivation fulfills a regulatory role in hydrogen peroxide signaling of eukaryotes. Interestingly, the presence of an ATP-dependent

enzyme, sulfiredoxin, able to reduce overoxidized peroxiredoxins back, stresses the importance of overoxidation of peroxiredoxins. Peroxiredoxins can undergo oligomerization, with the formation of ring-shaped complexes. However, the typical 2-Cys peroxiredoxins occur as homodimers and, in either their reduced or overoxidized forms, they can form decamers or dodecamers. The reduced oligomers are still redox active, whereas the overoxidized complex exhibits chaperone-like properties, helping to prevent protein aggregation.

In conclusion, heme and nonheme peroxidases make use of different active sites, such as the iron porphyrin prosthetic group, selenocysteine, or a deprotonated (reactive) cysteine. Other less common peroxidases containing vanadium or manganese at their active sites have also been described. This large variety of enzymes with active sites having different components and structures but with the unique function of removing H_2O_2 and other hydroperoxides emphasizes the physiological importance of this process and indicates that the cell cannot rely upon a single catalytic system when coping with peroxides.

Hydrogen Peroxide as a Signaling Molecule and the Controlling Role of Peroxidases

ROSs are not only responsible for oxidative stress, but, particularly at low levels, also considered to play an important role in normal cell metabolism, acting as modulators of redox-regulated processes. Several upstream effectors, such as growth factors, cytokines, insulin, and other hormones, are all able to activate signaling cascades by inducing the formation of superoxide and hydrogen peroxide. In turn, peroxidases endowed with the distinctive ability to scavenge hydrogen peroxide play a regulatory function in H_2O_2 signaling.

Glutathione peroxidases and peroxiredoxins are the terminal enzymes of the glutathione and Trx systems, respectively (Figure 4). The upstream reducing agent for both systems is reduced nicotinamide adenine dinucleotide phosphate (NADPH), which is kept reduced in the cytosol by the

reactions occurring in the hexose monophosphate pathway. In mitochondria, reducing equivalents are transferred from reduced nicotinamide adenine dinucleotide (NADH) to nicotinamide adenine dinucleotide phosphate ($NADP^+$) by the membrane-bound enzyme transhydrogenase. Glutamate and isocitrate dehydrogenases, capable of reducing $NADP^+$ directly, are further sources of this reduced coenzyme. In addition to NADPH, the glutathione system is also composed of glutathione reductase which, by keeping glutathione reduced, delivers electrons to glutathione peroxidase and to other proteins such as glutaredoxin and glutathione S-transferase (Figure 4). The Trx system is formed of NADPH, thioredoxin reductase (TrxR), and Trx (Figure 4). TrxRs are homodimeric proteins found in cytosol, mitochondria, and nucleus, characterized by a selenocysteine residue at their active site. TrxR reduces Trx in a reaction coupled with the oxidation of NADPH. Trx is a small redox protein with two cysteines in its active site, cycling between the reduced dithiol form ($Trx(SH)_2$) and the oxidized disulfide ($Trx(SS)$). It acts as an efficient reductant for several substrates and is a major donor of reducing equivalents for peroxiredoxins. Glutathione and Trx systems play an apparently similar role, but they act independently. An important difference is that glutathione, the main nonprotein thiol of the cell, is found at millimolar concentrations, whereas Trx occurs in the micromolar range.

One indication of the important role played by hydrogen peroxide in redox signaling is provided by the fact that overexpression of glutathione peroxidases or peroxiredoxins decreases the growth factor and cytokine-induced signaling, thus indicating that peroxidases can control H_2O_2 fluxes and hence the efficiency of the redox signal. This has been well described for platelet-derived growth factor receptor (PDGFR) and protein tyrosine phosphatase (PTP). Upon activation of the receptor, hydrogen peroxide is transiently produced and inactivates PTP molecules located close to the receptor. Consequently, phosphorylation is preserved and the growth signal is switched on. However, recruitment of peroxiredoxin by the receptor complex and the consequent removal of hydrogen

Figure 4 Glutathione and thioredoxin systems and their targets. The glutathione system is formed of glutathione, NADPH, and glutathione reductase; the thioredoxin system is composed of thioredoxin, NADPH, and thioredoxin reductase. Glutathione reductase and thioredoxin reductase transfer reducing equivalents from NADPH to glutathione and thioredoxin, respectively. Reduced glutathione acts as a substrate of glutathione peroxidase and of other enzymes such as glutathione S-transferase and glutaredoxin, which in turn, reduces ribonucleotide reductase, NF-κB, and other molecules. Similarly, thioredoxin, in addition to peroxiredoxin, can also transfer reducing equivalents to methionine sulfoxide reductase, ribonucleotide reductase, protein tyrosine phosphatase and other factors.

peroxide activate PTP, with a decrease in the growth signal. Similarly, peroxiredoxin prevents inactivation of the lipid phosphatase, phosphate and tensin homolog deleted from chromosome-10 (PTEN), induced by hydrogen peroxide.

Peroxiredoxins control not only the concentration of hydrogen peroxide but also the redox state of Trx, which is an important signaling event. For instance, after specific inhibition of TrxR and in the presence of hydrogen peroxide, Trx is almost completely oxidized by peroxiredoxin. In addition, oxidized Trx cannot be reduced back, as the inhibited TrxR is unable to transfer electrons from NADPH. Oxidized Trx can affect the functions of signaling molecules and alter membrane permeability. A well-known example is regulation of the apoptosis signal-regulated kinase-1 (ASK-1), belonging to the mitogen-activated protein kinase (MAP kinase) signaling pathway. ASK-1 is inhibited by reduced Trx, but this effect is lost upon oxidation of Trx. Inhibition of TrxR also leads to complete oxidation of Prx3, which may be responsible for increased permeabilization of mitochondrial membranes and the consequent release of proapoptotic factors. Lastly, overoxidation of peroxiredoxin, associated with its multimerization, address peroxiredoxins to a chaperone function which assists cells in recovery from the consequences of oxidative stress.

Peroxiredoxins can act as switches of oxidizing messages, as they are able to oxidize not only their thiol substrates but also other protein thiols. In this way, the highly reactive thiols of peroxiredoxins act as sensors of hydrogen peroxide and transfer this effect to other regulatory proteins which are otherwise unable to sense peroxides. In this case, the peroxidatic cysteine of peroxiredoxins, after oxidation to sulfenic acid, can interact with the cysteine of a transcription factor, leading to its activation. Trx regenerates both peroxiredoxin and the transcription factor to the native thiol forms. This thiol-oxidizing function of peroxidases has also been observed for Gpx4 in the formation of the capsula of spermatozoa.

In addition to removing hydrogen peroxide, peroxidases and catalase can also modulate cell signaling by association with a large number of regulatory proteins in a manner not necessarily dependent on their peroxidatic properties.

Concluding Remarks

Peroxidases are widely distributed peroxide-decomposing enzymes which carry out many physiological functions, not restricted to simple protective effects against potential peroxide toxicity. In addition to protective action, they also have

biosynthetic and immunological properties and modulate hydrogen peroxide signaling. They possess various catalytic sites such as heme, selenol, and thiol, with a unique reactivity toward peroxides. The extensive presence, wide distribution, and evolution of different mechanisms of catalysis of peroxidases reveal the importance of controlling the concentration and fluxes of hydrogen peroxide in living organisms.

Peroxisomal Metabolism

S J Gould, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Published by Elsevier Inc.

The peroxisome is a single membrane organelle present in virtually all eukaryotic cells. While the enzymatic composition and metabolic function of peroxisomes can vary from cell to cell, tissue to tissue, and organism to organism, there are a few common themes to peroxisomal metabolism in mammalian cells. First, peroxisomes catalyze the oxidation of fatty acids. In humans, peroxisomes contain two fatty acid β -oxidation pathways as well as a fatty acid α -oxidation pathway. These pathways are essential for degrading very long chain fatty acids ($\geq C22$), 3-methyl branched-chain fatty acids, and for synthesizing bile acids. These peroxisomal pathways do not fully degrade their substrates, but instead reduce them to medium-chain length fatty acids that are exported for further β -oxidation in the mitochondrion. As for the oxidation of fuel fatty acids (e.g., palmitate, oleate), this is primarily a mitochondrial role in mammals and other animals, though peroxisomes are the sole site of all fatty acid β -oxidation in yeast and plants. Second, mammalian peroxisomal enzymes catalyze several early steps in the synthesis of ether-linked lipids. Third, inactivating mutations in the genes that code for key enzymes and transporters involved in peroxisomal β -oxidation, α -oxidation, or ether lipid synthesis cause severe neurological disorders, including X-linked adrenoleukodystrophy, D-bifunctional protein deficiency, rhizomelic chondrodysplasia punctata, and Refsum disease. Fourth, defects in peroxisome biogenesis impair all three of these core peroxisomal metabolic processes and can cause the most severe of all peroxisomal diseases, Zellweger syndrome.

Peroxisome Biogenesis

The metabolic functions of peroxisomes are dependent upon the proper biogenesis of the organelle and its constituent proteins. Peroxisomes lack nucleic acids and all peroxisomal proteins are encoded by nuclear genes. In general, peroxisomal enzymes and metabolite transporters are synthesized in the cytoplasm and imported posttranslationally into the peroxisome, though there are differences in the import of peroxisomal membrane proteins (PMPs) and peroxisomal matrix proteins, including most peroxisomal enzymes.

Biogenesis of Metabolite Transporters and Other PMPs

PMPs contain *cis*-acting peroxisomal targeting signals, mPTSs. These targeting signals are relatively large, multipartite signals that contain at least one transmembrane domain and one high-affinity binding site for PEX19, a chaperone/import receptor for newly synthesized PMPs (peroxisome biogenesis factors are known as 'peroxins', and referred to by the acronym PEX, with a dedicated number for each factor). PEX19 binds newly synthesized PMPs in the cytoplasm, maintains their

solubility in the cytoplasm, and delivers them to the outer surface of the peroxisome by binding to PEX3, an integral PMP that functions as a docking factor for PEX19–PMP complexes. The next step in PMP import is poorly understood, but involves the dissociation of PMPs from PEX19 and their insertion into the peroxisome membrane. While there is some evidence that certain peroxins that reside in the peroxisome membrane can traffic to peroxisomes via the endoplasmic reticulum (ER), peroxisomal metabolite transporters appear to follow the direct cytoplasm-to-peroxisome route of PMP import that is mediated by PEX19 and PEX3.

Given their central roles in PMP import, it is not surprising that loss of either PEX19 or PEX3 blocks PMP import and the eventual loss of peroxisomes from the cell. In mammalian cells, loss of PEX16 causes a similar phenotype, and while PEX16 does not appear to be required for import of most PMPs, it does play an essential role in the import of PEX3 into the peroxisome membrane.

Biogenesis of Peroxisomal Enzymes and Other Matrix Proteins

In contrast to the PMPs, peroxisomal matrix proteins (including most peroxisomal enzymes) have to be transported across the peroxisome membrane. These peroxisomal matrix proteins possess different types of PTSs, the PTS1 and PTS2. Unlike the poorly conserved, multipartite mPTSs that target PMPs into the peroxisome membrane, the PTS1 and PTS2 are short, discrete peptide motifs. The PTS1 is a tripeptide located at the extreme C-terminus and typically has the sequence serine–lysine–leucine_{COOH} or a conservative variant. Almost all peroxisomal matrix proteins possess a PTS1. The PTS2 is a nonapeptide-targeting signal located at or near the N-terminus, and mediates the import of only a very small number of peroxisomal enzymes. These targeting signals are recognized by the PTS1 receptor PEX5 and the PTS2 receptor PEX7.

PEX5 and PEX7 bind their cargoes of newly synthesized peroxisomal enzymes in the cytoplasm and then deliver them to the peroxisome via high-affinity binding to a specific docking factor, the peroxin PEX14. Peroxisomal matrix protein import also requires at least a dozen additional peroxins that catalyze the translocation of peroxisomal enzymes into the peroxisome lumen, as well as the recycling of PEX5 and PEX7 to the cytoplasm. These include a pair of AAA adenosine triphosphatases (ATPases) (PEX1 and PEX6), a PEX6-docking factor (PEX15/PEX26), ubiquitin-conjugating enzymes (PEX4/UBC5a,b,c), a PEX4-docking factor (PEX22), RING-containing PMPs that function as ubiquitin E3 ligases (PEX2, PEX10, and PEX12), PEX14-associated PMPs (PEX13 and PEX17), specialized chaperones for PEX7 (PEX18/20 or a specialized PEX5 isoform), as well as peroxins of less-defined function and conservation (PEX8, PEX9, PEX21, etc.).

Diseases of Peroxisome Biogenesis

Inactivating mutations in the genes encoding key factors involved in PMP import or peroxisomal matrix protein import cause Zellweger syndrome, a severe inherited disorder that is characterized by loss of all major peroxisomal metabolic functions (fatty acid β -oxidation, fatty acid α -oxidation, bile acid synthesis, and ether-phospholipid synthesis), an array of neurologic, hepatic, and renal abnormalities, and neonatal death. Hypomorphic mutations cause a spectrum of related diseases (e.g., neonatal adrenoleukodystrophy and infantile Refsum disease) that present with slightly less severe symptoms. The term 'Zellweger spectrum' is used to describe patients along this continuum of genetic, cell biological, and biochemical defects in peroxisome biogenesis. Current evidence indicates that these patients suffer from defects in 12 genes (*PEX1*, *PEX2*, *PEX3*, *PEX5*, *PEX6*, *PEX10*, *PEX12*, *PEX13*, *PEX14*, *PEX16*, *PEX19*, and *PEX26*) and that defects in *PEX1* are responsible for disease in nearly two-thirds of Zellweger spectrum patients, in part, because of two relatively common *PEX1* alleles in patients of European descent.

In contrast to the Zellweger spectrum disease, inactivating mutations in *PEX7* causes a distinct disorder known as 'rhizomelic chondrodysplasia punctata (RCDP)' type 1, which is characterized by rhizomelia, ichthyosis, and pronounced mental retardation. This disease is defined by an inability to import PTS2-targeted peroxisomal proteins, and this leads to selective defects in peroxisomal fatty acid α -oxidation and ether-phospholipid synthesis, which reflects the PTS2- and PEX7-dependent import of one key enzyme in each of these pathways: phytanoyl-CoA 2-hydroxylase and alkylldihydroxyacetone phosphate synthase, respectively. Interestingly, isolated defects in ether-phospholipid synthesis enzymes present a phenocopy of type 1 RCDP and are referred to as RCDP type 2 and 3 (see below).

Peroxisome Division

The most common route for the formation of new peroxisomes is the budding/scission of pre-existing peroxisomes to generate one or more peroxisomes. In humans, this mode of peroxisome biogenesis appears to involve peroxins of the *PEX11* family (humans express three *PEX11*-like genes) and the dynamin-like guanosine triphosphatase (GTPase) *DLP1*. Targeted disruptions of the *PEX11 α* and *PEX11 β* genes have been generated in mice, and loss of the *PEX11 β* gene displayed a number of Zellweger spectrum-like phenotypes, including impaired neuronal migration, hepatic abnormalities, and neonatal death. Neither *PEX11* gene appeared to be required for cell viability, whereas *DLP1* activity is essential for cell survival, which likely reflects its critical role in mitochondrial fission, and potentially in other aspects of cellular membrane dynamics. Interestingly, an isolated dominant mutation in *DLP1* caused a unique human disease with defects in both peroxisomal and mitochondrial function, and defects in both mitochondrial and peroxisomal dynamics, an array of clinical phenotypes, including some that resembled those of Zellweger spectrum patients.

Formation of Peroxisomes *De Novo*

Peroxisomes can also be formed *de novo*, at least under certain conditions. This phenomenon has only been definitively

observed under specialized laboratory conditions in which cells lacking *PEX19*, *PEX3*, or *PEX16* subsequently receive a functional copy of the defective gene, either by gene delivery or by cell fusion. The pathway of *de novo* peroxisome biogenesis appears to be quite slow, raising questions as to whether it makes a substantive contribution to peroxisome formation under physiologically relevant conditions. Nevertheless, *de novo* peroxisome formation is a ubiquitous property of eukaryotic cells and has been reported in organisms as diverse as yeast and human cells. Current models propose that *de novo* peroxisome formation involves the release of vesicles from the ER, which subsequently mature into peroxisomes that are capable of subsequent growth and division. As for whether defects in *de novo* peroxisome biogenesis affect peroxisome metabolism, this question is difficult to resolve since the key factors in *de novo* peroxisome formation are *PEX19*, *PEX3*, and *PEX16*, peroxins that also play direct and essential roles in PMP import.

Metabolic Functions of Peroxisomes

The purpose of the peroxisome is to catalyze specific metabolic processes in ways that complement the other metabolic activities of the cell and enhance the fitness of the organism. While the existence of unique peroxisomal metabolic activities has been recognized for more than four decades, the past decade has witnessed a systematic analysis of peroxisomal protein content, enzymatic activities, and genetically impaired cells and organisms that have revealed the full scope, significance, and limitations of peroxisomal metabolism. Nevertheless, certain details of peroxisomal metabolism still remain to be resolved, particularly in regard to metabolite transport across the peroxisome membrane.

Peroxisomal Fatty Acid β -Oxidation

Peroxisomal fatty acid β -oxidation occurs in organisms as diverse as yeast, plants, invertebrates, and vertebrates. In fact, the peroxisomal fatty acid β -oxidation pathway is the sole fatty acid β -oxidation pathway in yeast and plants, as these organisms lack a mitochondrial fatty acid β -oxidation pathway. Although cells can express multiple isoforms of each enzyme, the core of the peroxisomal fatty acid β -oxidation pathway consists of these four basic steps:

1. Oxidation of a fatty acyl-CoA to a 2-enoyl-CoA. In the peroxisomal pathways, this reaction is catalyzed by an acyl-CoA oxidase, an enzyme that couples the oxidation of acyl-CoAs to the reduction of molecular oxygen into hydrogen peroxide (H_2O_2). This step represents the major enzymatic difference between the peroxisomal and mitochondrial fatty acid β -oxidation pathways. This difference has significant bioenergetic consequences, as the free energy of acyl-CoA oxidation by the peroxisomal pathway is lost to the environment, whereas the free energy of acyl-CoA dehydrogenation by the mitochondrial pathway can be coupled to mitochondrial electron transport and ATP synthesis, yielding an additional 1–2 ATP per turn of the fatty acid β -oxidation spiral.

2. The second step in the pathway is the hydration of 2-enoyl-CoAs to 3-hydroxyacyl-CoAs, catalyzed by enoyl-CoA hydratase. Peroxisomal forms of enoyl-CoA hydratase are expressed as multifunctional peroxisomal proteins (e.g., D-bifunctional protein, or DBP).
3. 3-Hydroxyacyl-CoA dehydrogenase activity. This enzyme catalyzes the NAD^+ -dependent dehydrogenation of 3-hydroxyacyl-CoAs, yielding the corresponding 3-ketoacyl-CoA and $\text{NAD(H)} + \text{H}^+$.
4. Thiolase-catalyzed cleavage of the 3-ketoacyl-CoAs, releasing acetyl-CoA (or propionyl-CoA in the case of 2-methyl-branched chain fatty acids) and an acyl-CoA that is two carbon units shorter than the initial substrate (or three carbon units shorter in the case of 2-methyl branched chain fatty acids).

In addition to these core enzymatic steps of fatty acid β -oxidation, peroxisomes contain a number of ancillary proteins that play important roles in fatty acid oxidation. These include:

1. Metabolite transporters that import acyl-CoA molecules from the cytoplasm to the peroxisome lumen, such as the PXA1/2 proteins of yeast and the ABCD1–4 proteins of human cells. These are members of the ATP-binding cassette (ABC) superfamily of ATPases.
2. Acyl-CoA synthetases that can activate certain free fatty acids to their acyl-CoA derivatives.
3. An adenosine triphosphate/adenosine diphosphate (ATP/ADP) carrier that supports the intraperoxisomal activation of selected fatty acids to their fatty-acyl-CoA derivatives.
4. Enzymes that rearrange double bonds prevent the oxidation of unsaturated fatty acids. These include 3-enoyl-CoA isomerase, which converts 3-enoyl-CoAs into 2-enoyl-CoAs that substrates of the hydratase enzyme. This isomerase is essential for the oxidation of unsaturated fatty acids with double bonds at odd-numbered carbons. For unsaturated fatty acids with double bonds at even numbered fatty acids, two additional enzymes are required: a dienoyl-CoA isomerase and a dienoyl-CoA reductase, which act together to generate 3-enoyl-CoAs, which can be converted to 2-enoyl-CoAs substrates by the 3-enoyl-CoA isomerase.
5. Racemase activities that convert 2R-branched chain fatty acids, which are not substrates for peroxisomal acyl-CoA oxidases, into their 2S stereoisomers, which are the only form that can be degraded by the peroxisomal enzymes.
6. Acetyl-CoA export mechanisms (e.g., carnitine acetyltransferase) that transport acetyl groups from the peroxisome lumen to the cytoplasm, a necessary first step for their subsequent oxidation in the mitochondrion.
7. Metabolite shuttles (e.g., malate dehydrogenase-based shuttles in yeast, lactate dehydrogenase-based shuttles in mammalian cells) that (a) regenerate the free NAD^+ required for continued dehydrogenation of 3-hydroxyacyl-CoAs and (b) move the reduced form of electron carriers out of the peroxisome, a first step toward their subsequent use in electron transport and ATP synthesis.

The peroxisomal fatty acid β -oxidation pathways in animals have a somewhat restricted metabolic role. This is perhaps most clear in humans and other mammals, where the peroxisomal fatty acid β -oxidation pathways play little, if any, role in

the oxidation of the major fuel fatty acids (e.g., C16 and C18 fatty acids) but are essential for the oxidation of very long chain fatty acids (e.g., C24, and especially C26), bile acid precursors such as di- and trihydroxycholestanic acid (DHCA and THCA, respectively), pristanic and other 2-methyl branched-chain fatty acids, as well as long-chain dicarboxylic fatty acids. Moreover, the peroxisomal fatty acid β -oxidation pathways in mammals are thought to shorten fatty acids to medium chain length rather than reduce them entirely to their acetyl-CoA (and propionyl-CoAs in the case of 2-methyl branched-chain fatty acids). Consistent with this model, peroxisomes contain a carnitine-octanoyltransferase that facilitates the export of medium-chain length fatty acids from peroxisomes for subsequent oxidation in the mitochondrion.

In contrast to animals and certain other organisms, the peroxisomal fatty acid β -oxidation pathway is the sole mechanism for converting fatty acids into acetyl-CoA in yeast and plants. This means that the peroxisomal pathway plays a key bioenergetic role in these organisms, particularly under conditions when fatty acids are the sole energy source. This occurs normally during germination of oil seeds, which use the energy released by peroxisomal fatty acid oxidation and acetyl-CoA production, together with the subsequent oxidation of acetyl-CoA by the mitochondrial tricarboxylic acid cycle, to power their germination and early stages of development. It also occurs in yeast, perhaps most commonly in parasitic/pathogenic yeast, and also in yeast that grow near natural oil seeps, oil spills, and even in fuel tanks of diesel-powered vehicles.

Diseases of Peroxisomal Fatty Acid β -Oxidation

Despite the somewhat restricted role for the peroxisomal fatty acid β -oxidation pathways in humans and other animals, these pathways are still critical for human metabolism and development. This point is perhaps most obvious from the severe phenotypes that result from inactivating mutations in the genes encoding human peroxisomal β -oxidation enzymes. For example, inactivation of the human *ACOX1* gene, which encodes one of the human acyl-CoA oxidases, causes hypotonia, seizures, neurological abnormalities, and premature death, even though it only affects the oxidation of very long chain fatty acids. Inactivation of the gene encoding the D-bifunctional enoyl-CoA hydratase/3-hydroxyacyl-CoA dehydrogenase (*HSD17B4*) gene causes an even more severe set of biochemical and clinical phenotypes, as it impairs the oxidation of almost all peroxisomal fatty acid β -oxidation substrates. Even defects in the peroxisomal 2-methyl-acylCoA racemase (encoded by the *AMACR* gene) result in clinical abnormalities, including a progressive loss of vision and other neurological abnormalities.

The most common human defect in peroxisomal fatty acid β -oxidation is caused by mutations in *ABCD1*, a gene located on the X-chromosome. This gene encodes an integral PMP that functions as a transporter for acyl-CoAs and is essential for the import of very long chain fatty acids into the peroxisome. Not surprisingly, inactivating mutations in *ABCD1* cause a pronounced accumulation of very long chain fatty acids throughout the body. Clinically, mutations in *ABCD1* can result in a spectrum of clinical phenotypes ranging from a

severe childhood disease, X-linked adrenoleukodystrophy, in which affected males develop normally until 5–8 years of age, and then undergo a rapid and progressive neurological deterioration that typically results in death within a few months, to a milder, later onset forms of the disease such as adrenomyeloneuropathy. Intriguingly, both the same mutations in *ABCD1* can give rise to dramatically different clinical phenotypes even in the same family, indicating that other loci and/or environmental factors can have a significant impact on the progression of this disease. As noted previously in the section on peroxisome biogenesis, defects in the import of PMPs or peroxisomal matrix enzymes can also cause significant defects in peroxisomal fatty acid β -oxidation.

Peroxisomal Contributions to Bile Acid Synthesis

As noted above, one class of substrates that is handled exclusively by the peroxisomal β -oxidation enzymes are the cholesterol-derived bile acid precursors DHCA and THCA. These large, lipophilic, 2-methyl branched chain fatty acids are first esterified with CoA, imported into the peroxisomal matrix, and then subjected to β -oxidation, release propionyl-CoA and choyl-CoA. Peroxisomes also contain a bile acyl-CoA: amino acid acyltransferase that transfers the bulky cholic acid moiety onto the amino acids taurine or glycine. This generates the bile acids that are subsequently exported from the peroxisome into the cytoplasm, and from the cytoplasm into the bile duct for subsequent delivery into the digestive tract.

Peroxisomal Fatty Acid α -Oxidation

Acting together, the core and ancillary enzymes of the peroxisomal and mitochondrial β -oxidation systems allow animals to oxidize a wide variety of dietary fatty acids. However, certain dietary fatty acids are resistant to β -oxidation, particularly 3-methyl substituted fatty acids such as phytanic acid (3,7,11,15-tetramethyl hexadecanoic acid). Nevertheless, animal cells rapidly oxidize these fatty acids due to the combined actions of (1) an exclusively peroxisomal fatty acid α -oxidation pathway, which shortens phytanic by one carbon and generates the 2-methyl branched-chain fatty acid known as pristanic acid and (2) the peroxisomal and mitochondrial fatty acid β -oxidation pathways, which degrade pristanic acid to acetyl-CoA and propionyl-CoA units.

Fatty acid α -oxidation pathway is a multistep process catalyzed by four peroxisomal enzymes:

1. Phytanic acid is activated to phytanoyl-CoA by a peroxisome-associated phytanoyl-CoA synthetase. There is some debate as to the location of this enzyme, and if it is located on the outer surface of the peroxisome, it seems likely that a metabolite transporter (possibly of the ABCD1–4 family) also plays a role in fatty acid α -oxidation.
2. The peroxisomal matrix enzyme phytanoyl-CoA 2-hydroxylase, a dioxygenase, converts phytanoyl-CoA hydroxylase to 2-hydroxyphytanoyl-CoA in a reaction that requires 2-oxoglutarate and oxygen.
3. 2-Hydroxyphytanoyl-CoA is degraded by 2-hydroxyphytanoyl-CoA lyase, releasing pristanal and formyl-CoA, which spontaneously decomposes to yield free CoA and formate, which subsequently evolves as CO₂.

4. Pristanal dehydrogenase catalyzes the NAD⁺-dependent oxidation of pristanal to pristanic acid, which is subsequently activated to pristanoyl-CoA, which is then subject to peroxisomal fatty acid β -oxidation.

As discussed above, the mammalian peroxisomal β -oxidation pathway only partially shortens its substrates, and this can be seen in the oxidation of pristanoyl-CoA (2,6,10,14-tetramethylpentadecanoyl-CoA) as well: three rounds of peroxisomal β -oxidation generate acetyl-CoA, 2 molecules of propionyl-CoA, and the branched-chain fatty acid 4,8-dimethylnonanoyl-CoA, which is then exported from the peroxisome for further oxidation in the mitochondrion. However, it is currently unclear whether this is mediated by the free fatty acid, a carnitine ester, or some combination of the two.

Refsum Disease

The importance of the fatty acid α -oxidation pathway in humans is evident from the severe disease that results from inactivating mutations in the phytanoyl-CoA 2-hydroxylase gene. Loss of this enzyme activity causes Refsum disease, which is characterized by early-onset retinitis pigmentosa, as well as a spectrum of more variable symptoms including deafness, neuropathy, ataxia, and heart disease. These manifestations are caused by the pronounced accumulation of phytanic acid, reaching levels as high as 30% of total body fatty acids. The phytanic acid that accumulates in this disease is of complex dietary origin. Humans acquire most of their phytanic acid through the consumption of meat, milk, and milk products (butter, cream, etc.) from cattle, goats, sheep, bison, yaks, camels, and other ruminants, sources that are rich in both phytanic acid and its precursor, the fatty alcohol phytol. As for the primary source of phytanic acid/phytol, it derives from the phytol side chain of chlorophyll. Phytol is cleaved from the chlorophyll molecule by rumen microorganisms (relatively little is released by nonruminant digestion of chlorophyll-containing foods). The free phytol generated in the rumen is typically oxidized to phytanic acid and incorporated into triglycerides and phospholipids. Consistent with this dietary origin for phytanic acid/phytol, dietary therapies that minimize the ingestion of ruminant-derived foods have therapeutic benefits for Refsum disease patients.

Ether–Phospholipid Biosynthesis

The classic structure of phospholipids is based on glycerol-3-phosphate esterified with fatty acids on its 1 and 2 carbons. However, ~15–20% of phospholipids in humans have a distinct structure in which a fatty alcohol is attached to the 1 carbon through an ether linkage. These ether-linked phospholipids are synthesized by the concerted action of enzymes that are located in the peroxisome, cytoplasm, and ER. The earliest enzymes in the pathway are located in/on the peroxisome, and these peroxisomal enzymes generate the alkyl-dihydroxyacetone phosphate (alkyl-DHAP) that serves as the essential precursor for ether–phospholipid synthesis. The key steps are:

1. A peroxisomal glycerol-3-phosphate dehydrogenase that oxidizes glycerol-3-phosphate to generate DHAP.

2. An intraperoxisomal DHAP acyltransferase that catalyzes the formation of 1-acyl-DHAP from DHAP and a fatty acyl-CoA. The acyl-DHAP released by this enzyme is one of the two substrates for the synthesis of alkyl-DHAP.
3. An NADPH-dependent fatty acyl-CoA reductase, located on the outer surface of peroxisomes, reduces acyl-CoAs to fatty alcohols, which are the other key substrate for making alkyl-DHAP.
4. Alkylidihydroxyacetone phosphate synthase, located in the peroxisome lumen, catalyzes the formation of 1-alkyl-DHAP using 1-acyl-DHAP and a fatty alcohol as its substrates and also releases a free fatty acid.
5. Alkyl-DHAP reductase, located on the cytoplasmic surface of both peroxisomes and the ER, catalyzes the NAD^{+} -dependent formation of 1-alkyl-glycerol-3-phosphate (1-alkyl-G3P).

In subsequent ER-localized reactions, 1-alkyl-G3P is converted to 1-alkyl-2-acyl-G3P, and after several additional steps, to 1-alkyl-2-acyl-glycerophosphatidylcholine and 1-alkyl-2-acyl-glycerophosphatidylethanolamine that make up the bulk of ether-linked phospholipids in mammalian cells.

RCDP is Caused by Defective Ether Phospholipid Synthesis

As with the other main peroxisomal metabolic functions, inactivating mutations in the genes encoding DHAP acyltransferase of alkyl-DHAP synthase cause severe human disease: RCDP type 2 and type 3. These diseases are clinically similar to RCDP type 1, which is caused by defects in the PTS2 import receptor, PEX7, and present with rhizomelia, ichthyosis, and pronounced mental retardation. The phenotypic similarities between type 1, 2, and 3 RCDP indicates that type 1 RCDP is caused primarily by the defect in ether-phospholipid synthesis. While the clinical similarities between a defect in PTS2 protein import and a defect in ether-phospholipid synthesis might not be immediately obvious, they make more sense when one considers that (1) alkyl-DHAP synthase is a PTS2-targeted protein and is imported into peroxisomes in a PEX7-dependent manner and (2) Refsum disease is a later onset, milder disease than RCDP and, thus, the consequences of defective fatty acid α -oxidation (phytanoyl-CoA 2-hydroxylase is also imported in a PTS2- and PEX7-dependent manner) in the RCDP type 1 patients are overshadowed by the more severe consequences of defective ether-phospholipid synthesis.

Additional Peroxisomal Enzymatic Functions

Peroxisomes also contain several enzymes that perform important cellular functions, yet lie beyond the scope of the core metabolic pathways outlined above. These include a large number of H_2O_2 -producing oxidases, including L- α -hydroxyacid oxidase, sarcosine/pipecolic acid oxidase,

D-amino acid oxidases, and (in nonprimates) urate oxidase. Complementing these peroxisomal oxidases are an array of antioxidative peroxisomal enzymes, including catalase, peroxiredoxin V, Cu/Zn-superoxide dismutase, epoxide hydrolase, and a glutathione S-transferase, as well as ancillary redox reactions that balance electron flow within the peroxisome and between the peroxisome and the cytoplasm (e.g., isocitrate dehydrogenase). Such systems presume the existence of specific metabolite carriers and/or a selective permeability of the peroxisome membrane to the requisite metabolites, both of which have empirical support. Although there has always been strong interest in the concept that the peroxisome's primary role is to serve as a protected site for the metabolism of reactive oxygen species, this hypothesis has thus far failed to receive strong genetic support, as disruption of catalase has little, if any, phenotypic consequence in mice. In fact, the only human disease that is caused by a defect in one of these additional peroxisomal enzymes is primary hyperoxaluria type 1. This disease, which is characterized by lethal accumulation of calcium oxalate kidney stones, is caused by defects in the peroxisomal alanine:glyoxylate aminotransferase, which uses alanine to donate an amino group to glyoxylate, releasing the glycine and pyruvate. In the absence of peroxisomal alanine:glyoxylate aminotransferase activity, glyoxylate is instead converted to oxalate, with severe pathological consequences.

Glossary

Fibrates A group of compounds that act as agonists for peroxisome proliferator-activated receptor alpha (PPAR α).

Peroxisome proliferator-activated receptors

(PPARs) These are ligand-activated transcription factors,

which alter gene expression to confer distinct properties of lipid handling to the tissues in which they are found, with an overall systemic lipid-lowering effect.

Thiazolidinediones (TZDs) A group of compounds that act as agonists for PPAR γ .

Lipids (triacylglycerol (TAG), cholesterol, phospholipids, fatty acids (FAs), and ketone bodies) are essential for many aspects of cellular processes, while also being linked to many pathological processes. Due to the varying demands of individual tissues for lipids, a highly regulated lipoprotein highway transports lipids to and from the periphery. The peroxisome proliferator-activated receptors (PPARs), α , γ , and δ , act as primary 'metabolic' transcription factors, responding to FAs and other metabolic signals to alter gene expression and thereby to confer distinct properties of lipid handling to the tissues in which they are found, with an overall systemic lipid-lowering effect. Thus, the PPARs act as a team with a common goal, but possess different attributes, including regulation of fat breakdown by oxidation (PPAR α and PPAR δ), regulation of adipocyte differentiation and fat storage (PPAR γ), together with other functions that include regulation of cholesterol fluxes into and out of cells (PPAR γ and PPAR δ).

Lipids are essential for many aspects of cellular processes, including acting as substrates for energy production, steroid hormones, and cellular structures. However, the availability and utilization of the various lipids must be carefully regulated because they are also linked to many pathological processes, including the development of obesity. The most familiar biological lipids are triacylglycerol (TAG), which serve as principal energy stores, and cholesterol, both of which are present in the circulation at detectable levels. Because the hydrophobic lipids do not dissolve in water, moving them around the body requires transport mechanisms that are highly regulated. Due to the variable requirements for these compounds from a wide range of tissues, a lipoprotein highway exists that allows transport of the hydrophobic lipids with water-soluble protein escorts enabling the movement of TAG and cholesterol to and from the periphery. TAG-enriched lipoproteins, chylomicrons (containing TAGs made from the reesterification of newly absorbed FA and monoacylglycerol (MAG) in the gut) and very-low-density lipoproteins (VLDLs) (containing TAG fabricated in the liver), deliver TAG to peripheral tissues for storage and energy production. The utilization by individual tissues of TAG in VLDL and chylomicrons is carefully regulated through the expression of lipoprotein lipase (LPL), which is anchored to the outside of the cell in which it is expressed. LPL liberates FA and MAG in TAG for uptake by the tissue.

Consequently, individual tissues can regulate their uptake of TAG-derived FA by altering the level of expression of LPL. At the same time, low-density lipoproteins (LDLs) deliver cholesterol to tissues so that they can maintain membrane integrity and, in some instance, use it for the production of biologically important compounds, such as steroids. Cholesterol uptake by cells is also regulated, in this case by the expression of the LDL receptor. In addition to the lipid highway from the liver/gut to peripheral tissues, a counter-flow operates in the opposite direction, whereby high-density lipoproteins (HDLs) transport surplus cholesterol from cells, such as those of the vessel wall, to the liver, where it can be redeployed to form bile. Gridlock in these lipid transfer and utilization systems leading to the accumulation of VLDL and LDL in the circulation is integral to the development of metabolic diseases, including type 2 diabetes mellitus (T2DM) and cardiovascular disease.

PPARs: A Three-Pronged Attack

PPARs are transcription factors, activated by binding metabolic ligands, which exert their effects at the level of DNA to alter gene expression. There are three PPAR subclasses (α , γ , and δ); each of these plays a specific role in metabolic regulation. PPARs were originally identified by their ability to induce peroxisome proliferation, and this led to the current nomenclature. PPAR α was first identified as the intracellular target for a particular class of rodent hepatocarcinogens, which include clofibrate. Clofibrate, a member of the fibrate amphipathic carboxylic acid family, was found to be a potent inducer of proliferation of peroxisomes, cell organelles found in high quantities in the liver, in addition to increasing FA oxidation and lowering lipid levels. Several other 'peroxisome proliferating' agents were subsequently cloned. However, it has since emerged that the PPARs do not induce peroxisome proliferation in man, but have an array of additional functions, most notably as master regulators of genes involved in metabolic control, particularly those involved in whole-body lipid homeostasis. Inappropriately, the name PPAR has remained in common use! The PPAR subtypes are distributed nonuniformly in tissues. PPAR α is expressed in a wide range of tissues and is highly expressed in liver, kidney, and heart. PPAR γ has a

more limited tissue distribution and is highly expressed in adipocytes and macrophages. PPAR δ is widely expressed. After the PPARs are activated by binding specific ligands and/or by covalent modification (phosphorylation), they bind to another receptor, the 9-*cis* retinoic acid-activated receptor (RXR), and conjoined and active, recruit coactivators and together bind to peroxisome proliferator response elements to modify the expression of specific genes. This leads to an altered complement of enzymes in the cell, with a resultant alteration in cellular functional characteristics. Through this mechanism, each PPAR can, once activated, confer distinct properties of lipid handling to the tissues in which it is found, with an overall systemic lipid-lowering effect. The individual PPARs act to reinforce each other's activities and also have complementary individual activities, all of which are concerned with the removal of excess lipid from the blood. Acting as a team with a common goal but differing attributes, the functions of the PPARs include regulation of fat breakdown by oxidation (PPAR α and PPAR δ), regulation of adipocyte differentiation and fat storage (PPAR γ), together with others that include regulation of cholesterol fluxes in to and out of cells (PPAR γ and PPAR δ). The molecular messengers that bind to and activate the individual PPARs (the endogenous ligands) are not all identified. However, the close involvement of fat metabolism and lipid homeostasis with the PPAR family members arises, in part, because certain FAs and other lipid-derived molecules, including eicosanoids and arachidonic acid derivatives, can activate PPARs and are known to be primary natural ligands for these molecules. For example, PPAR α is activated by polyunsaturated FAs, and PPAR δ by long-chain FAs. Thereby, these lipid-signaling molecules can have power over their own fates by binding to PPARs and changing the expression of genes involved in modulating the patterns of tissue FA handling. The physiological importance of the PPARs, thus, resides in lipid management, and the clinical importance of drugs acting via the PPARs lies in their ability to mimic nature's own messengers when the task of lipid management becomes too onerous and harmful lipids accumulate. It is now established that the fibrates (e.g., clofibrate) and the antidiabetic insulin-sensitizing thiazolidinediones (TZDs) both exert their systemic lipid-lowering effects via the PPARs. In this article, we focus on how these receptors modulate lipid homeostasis in metabolically active tissues.

Peroxisome Proliferator-Activated Receptor Alpha

Too much FA, TAG, or cholesterol circulating in the blood can be hazardous to health. High-fat diets, particularly those rich in very-long-chain FAs and polyunsaturated FAs, induce FA oxidation via PPAR α . Synthetic ligands for PPAR α , in addition to the fibrate drugs, include phthalate ester plasticizers, herbicides, and leukotriene D4 receptor antagonists. The fibrate PPAR α agonists (clofibrate, gemfibrozil, fenofibrate, bezafibrate, and ciprofibrate) have been in clinical use for over 40 years for the treatment of dyslipidemia.

The liver occupies a central position in whole-body lipid handling. In the case of FAs, the liver is capable of either oxidizing, or storing FAs depending on the prevailing requirements.

FAs are stored after conversion to the TAG component of VLDL, and this function can be increased when FA delivery is higher than that required to fuel hepatic adenosine triphosphate (ATP) requirements via β -oxidation. Incoming FAs, derived from the diet or endogenous stores, are reesterified and stored in the fed state. During starvation, FAs, released from adipose tissue, are taken up by the liver and oxidized to create the water-soluble lipid-derived fuels, the ketone bodies (which are easily transported and oxidized by peripheral tissues), while TAG is incorporated into VLDL which is released into the circulation. These latter metabolic transformations of incoming FAs are enhanced by PPAR α , the primary PPAR subtype expressed in liver. PPAR α regulates specific genes that code for regulatory proteins involved in almost every stages of hepatic FA utilization, including FA uptake into the cell across the cell membrane (FA transport proteins), its retention within the cell, and its oxidation leading to ATP production and ketone body formation (Figure 1). It also plays a role in lipoprotein formation and cholesterol synthesis. PPAR α , therefore, fulfills a critical role in the regulation of hepatic FA handling and, indeed, is essential for the upregulation of the capacity of the liver for FA utilization in starvation or when lipid delivery is increased by a diet high in fat. This adaptive role is best illustrated by the inadequate response to high-fat feeding seen in PPAR α -deficient mice, the Jack Sprats of lipid biochemistry. These animals exhibit an impaired ability to upregulate hepatic FA oxidation in response to a high-fat diet, despite increases in FA supply, and the liver becomes engorged with lipid. Similarly, PPAR α -deficient mice are unable to adapt to starvation, where delivery of FA from adipose tissue is increased. Secondary to impaired FA oxidation, compromised hepatic energy generation results in a low blood glucose concentration (hypoglycemia) when PPAR α -deficient mice are fasted. Hypoglycemia arises by virtue of the necessity to continue to use glucose at high rates, rather than to be able to switch to FA or (in extrahepatic tissues) ketone bodies as alternative energy fuels, and because hepatic FA oxidation allows hepatic glucose synthesis (gluconeogenesis) through the generation of ATP and essential cofactors. The accumulation of large amounts of lipid in livers of PPAR α -deficient mice, either on fasting or when they are maintained on a high-fat diet, demonstrates the critical importance of PPAR α -linked functions in matching hepatic FA delivery to FA clearance when the systemic delivery of lipid is increased. Hence, the TAG-lowering action of fibrates and related PPAR α -targeted drugs in patients with hyperlipidemia is ascribed to increased FA clearance via oxidation, primarily but not exclusively in liver. Within the liver, PPAR α is also heavily involved in the regulation of the synthesis and catabolism of lipoproteins, including some steps of the HDL synthetic pathway. Increased diversion of FA into oxidation decreases the availability of fatty acyl-coenzyme A (CoA) substrates for TAG synthesis, and thereby decreases VLDL secretion by the liver. In addition, PPAR α inhibits expression of apolipoprotein (apo) C-III (a protein that may inhibit the TAG-hydrolyzing action of LPL) and so enhances the hydrolysis of TAG contained in lipoproteins, and increases the hepatic uptake of TAG-enriched lipoprotein remnants. This decreases plasma TAG levels further and increases the transfer of other surface components of TAG-rich particles to HDL.

Figure 1 Mechanisms whereby activation of PPAR α regulates fatty acid uptake, sequestration in the cell and oxidation.

More recently, PPAR α studies have focused on elucidating the regulatory mechanisms governing PPAR α -mediated induction of gene expression. In particular, the essential role of PGC1 α has been described. PGC1 α interacts with PPAR α to induce expression of PPAR α target genes, for example, that encoding the rate-limiting enzyme for the transport of FA into the cellular organelles where they are further metabolized. This process is enhanced by several other regulators, such as sirtuin 1 (SIRT1) and lipin-1. SIRT1 is an enzyme involved not only in the regulation of cellular metabolism, but also in the responses to stress and the modulation of life span. SIRT1 activation in mice protects them against obesity induced by feeding a high-fat diet. Importantly, activation of an axis involving SIRT1 and an enzyme that senses metabolic stresses such as fuel starvation (adenosine monophosphate-activated protein kinase; AMPK) increases FA oxidation by covalent modification of their targets. SIRT1 is reported to deacetylate and activate PGC1 α , leading to induction of PPAR α -mediated expression of FA-oxidation genes, while liver-specific SIRT1 knockout mice develop a fatty liver when fed a high-fat diet. However, in a separate study, SIRT1-mediated induction of PGC1 α was shown to induce gluconeogenesis, while knockdown of SIRT1 and PGC1 α lowered blood glucose in normal and diabetic mice. These two studies highlight the problems of PPARs as a therapeutic tool for treatment of metabolic syndrome.

Another protein, lipin-1, is implicated in the regulation of cellular lipid homeostasis in several tissues, including liver. Lipin-1 regulates both intracellular lipid synthesis (through functioning as an enzyme, phosphatidate phosphatase-1 (PAP-1), producing an important glycerolipid building

block) and lipid clearance (by activating lipid regulation of gene expression). The role of lipin-1 in transcriptional coactivation was uncovered in a mouse model of PGC1 α deficiency. Within this latter context, lipin-1 expression is induced by PGC1 α and additionally lipin-1 also plays a key role in PPAR α regulation, functioning to induce PPAR α gene expression as well as interacting with and amplifying PGC1 α -PPAR α -mediated gene expression. The involvement of lipin-1 in this regulatory circuit leads to further confusion regarding the suitability of PPAR agonists as therapies for T2DM. Lipin-1 has been reported to increase TAG synthesis and is increased in diabetic mouse models, while knockdown of lipin-1 corrects insulin-resistant mice. Moreover, lipin-1 interacts with other nuclear factors, including hepatocyte nuclear factor 4 α (HNF4 α), a key transcription factor for induction of gluconeogenic genes.

Further studies will attempt to elucidate the mechanisms by which PPAR α -PGC1 α mediate gene expression, with particular focus on the roles of SIRT1 and lipin-1. This is of particular clinical relevance given that agonists of both PPAR α and SIRT1 are currently under investigation as therapies for T2DM.

As well as in liver, PPAR α is expressed abundantly in other tissues that are normally characterized by high rates of lipid oxidation. It is also present in the artery wall in monocytes/macrophages, vascular smooth muscle cells, and endothelial cells. We focus here on the role of PPAR α in kidney and heart, tissues which have a high-energy demand related to their physiological functions. In these tissues, PPAR α activation again enhances the expression of genes involved in FA uptake, activation, and oxidation. PPAR α -deficient mice subjected to ischemia/reperfusion injury respond with greater renal cortical

necrosis and impaired kidney function compared with wild-type controls, indicating the vital role of PPAR α in this tissue. PPAR α is found predominantly in the renal cortex. Like liver, the renal cortex is a site of gluconeogenesis. Altered renal gluconeogenesis is increasingly recognized as contributing to fasting hyperglycemia in diabetes mellitus, and assumes increasing importance for maintenance of glycemia after very prolonged food deprivation. Hence, as in liver, PPAR α -facilitated gluconeogenesis driven by enhanced FA oxidation is likely.

Although functionally quite distinct from liver and kidney, there is ample evidence for an important role for PPAR α in cardiac function in some circumstances. In adulthood, although the heart is a metabolic omnivore using most available fuels, lipids constitute the predominant energy substrate. However, during fetal and early life, in cardiac hypertrophy and in the failing heart, glucose utilization assumes greater importance, possibly as an adaptation to limited oxygen availability. Oxygen is essential for ATP production from FAs, but glucose oxidation needs less oxygen per mole than FA oxidation and glucose utilization can proceed, albeit less efficiently, in the absence of oxygen. The downside is that less ATP is generated per mole of glucose oxidized and when excess dietary lipid can be ingested, as in life after birth, the potential exists for myocardial lipid accumulation and lipotoxicity. Accordingly, the importance of PPAR α in the adult heart appears relatively limited when the dietary lipid supply or endogenous lipid production is restricted, but PPAR α assumes an important role in cardiac lipid management when lipid delivery to the heart is increased. PPAR α -deficient mice provided with free access to a high-carbohydrate low-fat diet do not show any obvious cardiac abnormalities, but they accumulate myocardial lipid on starvation or if a high-fat diet is provided. This indicates a vital function for PPAR α in allowing cardiac FA oxidation to occur at a rate sufficient to prevent the harmful accumulation of lipid within the heart itself.

Changes in the activity of the PPAR α signaling pathway to gene expression characterize many common myocardial diseases. Whether changes in cardiac PPAR α signaling are adaptive or causally related to myocardial pathology remains controversial, but there is no doubt that poor lipid management can cause a broken heart! Cardiac PPAR α expression and activity are suppressed in the pathologically hypertrophied heart. The resultant decrease in the capacity for FA oxidation is associated with increased rates of glucose utilization and reversion to the fetal pattern of substrate use. Although causality between the reciprocal changes in lipid and glucose utilization has not been established, this metabolic switch may serve to preserve ventricular function within the context of pressure overload. The expression and activity of both PPAR α and RXR are also suppressed in the hypoxic cardiac myocyte. To date, there are no reports of worsening cardiac function in humans with cardiac hypertrophy through the use of the PPAR α agonist fibrates. It is interesting that the heart is closely associated with adipose tissue in adult man, and epicardial and pericardial depots can represent a significant fraction of the total mass of the heart, suggesting a possible role as a local FA source. Both neutral lipid and FA adversely affect myofibrillar function. An intriguing possibility is that cardiac adipose tissue may act as a potential local sink for FA, mopping up FA when they are delivered in excess of the cardiac ATP requirement or when

they cannot be cleared through oxidation, for example, during cardiac hypertrophy.

Epidemiological studies reveal that people with diabetes are at an extraordinary high risk for the development of cardiovascular disease. The heart in uncontrolled diabetes is constrained from switching to glucose oxidation and relies almost exclusively on lipid as an energy source. Cardiac-specific overexpression of PPAR α , in the absence of alterations in lipid-fuel delivery, enhances the myocardial capacity for FA oxidation. This, however, is maladaptive, because many of the metabolic abnormalities of the diabetic heart, including decreased glucose utilization and ventricular dysfunction, are recapitulated. In this situation, the profile of myocardial TAG species is similar to the lipid species in the circulation, suggesting that the expanded lipid reservoir reflects increased uptake incompletely balanced by a corresponding increase in oxidation. When mice with cardiac-specific PPAR α overexpression are made diabetic, they develop a more severe cardiomyopathy than wild-type controls. By contrast, PPAR α null mice are protected from this cardiomyopathy.

Peroxisome Proliferator-Activated Receptor Gamma

PPAR γ is the predominant molecular target for the insulin-sensitizing TZDs and for specific prostanoids, such as 15-deoxy- $\Delta^{12,14}$ prostaglandin J2. It is abundantly expressed in fat cells (adipocytes), macrophages, the placenta, and the fetal heart. The role of PPAR γ as a critical regulator of adipocyte development and fat storage is perhaps most well established of the functions of the PPARs. Adipocytes expand as animals fatten, then shrink when the stored TAGs within them are mobilized because of food scarcity or, in the case of Mrs Sprat or the Atkins diet, lack of carbohydrate. A key feature of the fat cell is its ability to release the FA derived from TAG into the bloodstream: most other tissues are less altruistic and use FA derived from their endogenous TAG. Detectable changes in gene expression in response to PPAR γ activation in the fat cells of adipose tissue include the induction of genes that allow them to take up and accumulate lipid (Figure 2). Through this action, PPAR γ contributes to lowering of circulating FA and TAG levels and, by sequestering lipid in the adipocyte, reduces the burden of excessive lipid delivery to tissues other than adipose tissue, including heart, skeletal muscle, kidney, and liver, where its accumulation could have deleterious effects. PPAR γ can, therefore, enhance whole-body insulin action even though it is predominantly expressed in adipose tissue (which makes a relatively minor contribution to insulin-stimulated glucose disposal in lean individuals) by limiting the supply of lipid to other insulin-sensitive tissues and reducing the ability of FA to oppose insulin's actions in these tissues.

In addition to effects on genes involved in adipocyte lipid storage, TZDs increase adipocyte expression of the insulin-sensitive glucose transporter GLUT4, which allows increased use of circulating glucose for the synthesis of glycerol-phosphate which, in turn, allows FA esterification to form storage TAG (Figure 2). Moreover, the TZDs may actually induce the fat cell to express enzymes that promote glycerol released from TAG breakdown (lipolysis) to be reclaimed or synthesized from circulating lactate, a process termed glyceroneogenesis

Figure 2 Mechanisms whereby activation of PPAR γ regulates fatty acid uptake, sequestration and storage, and glucose uptake and glycerogenesis in adipocytes.

(Figure 2). The presence of glycerol kinase allows glycerol released via the hydrolysis of stored TAG to be converted to glycerol phosphate which, in turn, allows reincorporation of released FA, or of FA derived from exogenous lipoproteins, into storage TAG, albeit at an energetic cost to the adipocyte. However, in obese people, as much as half of the body mass can be adipose tissue due to excessive enlargement of adipocytes and the presence of increased numbers of adipocytes. Obese people invariably become glucose intolerant and insulin resistant, as well as developing other obesity-related complications that increase morbidity and mortality. “We fat all creatures else to fat us, and we fat ourselves for maggots” (Hamlet). It follows that the long-term use of TZDs could actually exacerbate obesity and insulin resistance, despite its more acute beneficial insulin-sensitizing action due to adipose-tissue lipid sequestration.

An additional action of PPAR γ activation in adipose tissue is altered rates of secretion of biologically active adipokines (signaling molecules secreted by adipocytes), including leptin and tumor necrosis factor- α (TNF α), which can modulate insulin sensitivity in nonadipose tissue. Both leptin and TNF α have a role in obesity. Samples of adipocytes from obese people produce much more TNF α than those from lean people. Leptin is a molecule that informs the brain that adipose tissue is replete with lipid and signals a need to cease eating. PPAR γ suppresses the production of both leptin and TNF α by human adipose tissue, thereby fooling the adipocyte that enough (lipid) is not enough, and allowing the adipocyte to continue to accumulate even more lipid.

Effects of the TZDs to ameliorate hyperglycemia and hyperlipidemia in fatless mice demonstrate that, although

predominantly expressed in adipose tissue, PPAR γ activators may exert their effects via PPAR γ in tissues in addition to adipose tissue. PPAR γ activators have been reported to be cardioprotective against ischemic insult and to modify the cardiac hypertrophic growth response to pressure overload. However, most cardiac effects are likely to be indirect because of the low level of expression of PPAR γ in cardiac myocytes themselves in adulthood, although the adipose tissue surrounding the heart itself may be targeted directly and act as a lipid buffer. The beneficial versus adverse effects of PPAR γ activators, however, remain controversial.

Most kinds of mammalian cells synthesize adequate cholesterol for their needs, but the human diet usually contains more than enough to supply our cells. Only the liver can degrade and eliminate cholesterol, so any excess has to be transported there from other tissues. LDL particles are rich in cholesterol. Some LDL leak through the thin lining of major vessels, where they become trapped under the endothelial cells, a process facilitated by hypertension (high blood pressure). Trapped LDL molecules attract macrophages, immune cells that can take up and degrade LDL. Some trapped LDL react with oxygen in the blood. Unfortunately, the oxidized LDL molecules appear to be able to enter the macrophages in almost unlimited quantities, accumulating as pale, greasy particles that resemble the appearance of foam. Death of the lipid-bloated macrophages (foam cells) releases their lipid content forming fatty streaks in the arteries. The endothelial cells covering the fatty streaks can become damaged and are replaced with fibrous plaques, narrowing the arteries. In the final stages of cardiovascular disease, the stiff narrow arteries ulcerate, increasing the risk of forming a

blood clot, which will plug blood flow completely. The increased risk of cardiovascular disease in diabetic patients has prompted study of PPAR γ function in lipid-laden macrophages. It has been reported that activation of PPAR γ with the TZDs promotes cholesterol efflux from macrophages, improving the status of the atherosclerotic lesion, whereas macrophages lacking PPAR γ are defective in cholesterol efflux and display accelerated lesion progression. Activation of PPAR γ by components of oxidized LDL (9-hydroxyoctadecadienoic acid, 13-hydroxyoctadecadienoic acid), however, enhances macrophage lipid accumulation through induction of a scavenger receptor/transporter (FA translocase/CD36).

Peroxisome Proliferator-Activated Receptor Delta

Compared with PPAR α and PPAR γ , relatively little is known about PPAR δ (also called PPAR β or FA-activated receptor), except that it is relatively ubiquitously expressed. Nevertheless, the importance of PPAR δ is established by the observation that most PPAR δ -deficient mice die early in embryonic development due to a placental defect and those few that do survive have a reduced fat mass. PPAR δ may also be involved in the cellular differentiation and inflammatory response of the epidermis. Importantly, PPAR δ has been shown to mediate VLDL signaling to gene expression in the roving macrophages. Exposure of macrophages to VLDL results in enhanced expression of a lipid-droplet-coating protein that is implicated in lipid storage in these cells. Studies of PPAR δ -deficient macrophages reveal that the TAG components of VLDL, released by LPL, serve as direct ligands for PPAR δ to induce this protein, with accompanying lipid accumulation within the macrophage. These new data reveal a pathway whereby VLDL itself can directly regulate gene expression in atherosclerotic lesions.

Pharmacological activation of PPAR δ lowers fasting TAG and LDL levels while increasing levels of HDL (the cardioprotective lipoprotein). It is unclear which tissue is targeted although skeletal muscle, in which PPAR δ is highly expressed, is suspected. Slow-twitch oxidative skeletal muscles (e.g., the postural muscles and muscles used during endurance exercise) are a major site of FA catabolism, particularly during starvation and long-term exercise, when circulating lipid delivery increases. However, most evidence suggests that signaling via PPAR α impacts predominantly on the regulation of lipid gene expression and fat burning in fast-twitch skeletal muscles, recruited during explosive exercise such as sprinting, even though fast-twitch muscles do not normally oxidize FA as avidly as slow-oxidative muscles. Whereas PPAR α ablation in the mouse results in abnormally high accumulation of neutral lipid in heart and liver in response to interventions increasing FA delivery, such as starvation, starvation of PPAR α -deficient mice leads to only minor abnormalities of skeletal-muscle FA metabolism. The lack of accumulation of neutral lipid has been attributed to the findings that PPAR δ is the major type of PPAR found in mouse skeletal muscle. PPAR δ may, therefore, assume greater importance in the modulation of lipid metabolism than PPAR α in skeletal muscle, a conclusion supported by findings that PPAR δ messenger RNA expression levels in muscle are dramatically increased on fasting, under conditions where FA oxidation by skeletal muscle is increased.

Interestingly, PPAR δ is also relatively abundant in the heart and exposure of cardiac myocytes to either PPAR α - or PPAR δ -specific agonists leads to significant induction of PPAR target genes involved in FA uptake and oxidation, and both PPARs can be activated by FAs within this system.

Current and Potential Therapeutic Roles for PPAR Activators

For some time, PPAR activators have been used for the treatment of dyslipidemia, particularly when the patients are likely to develop heart disease. PPAR α also allows protection at the vascular atherosclerotic site; this is particularly efficacious in patients with dyslipidemia due to T2DM. As a result of the many benefits of PPAR γ activation with respect to maintenance of glucose and lipid homeostasis described above, TZDs are currently licensed for use in the management of T2DM. The first TZD to be approved, troglitazone, is no longer in use due to liver toxic effects. However, two other TZDs, pioglitazone and rosiglitazone, have been shown to lower blood glucose and are currently approved as antihyperglycemic agents. However, recent controversy has emerged regarding the safety of the TZD class of drugs, particularly rosiglitazone. Side effects of TZDs include worsening of heart failure, fluid retention, and weight gain, and so treatment using this drug is closely monitored. Indeed, TZDs are contraindicated in patients with certain types of heart failure. Moreover, a recent study comparing clinical effects of TZDs reported significantly increased relative risks of a heart attack or cardiovascular death with rosiglitazone. This revelation led to the precautionary removal of rosiglitazone from use in the Veterans Affairs Diabetes Trial (VADT), a large-scale clinical trial of antihyperglycemic therapies. Despite this, the final analysis of the VADT and two other similar trials, Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease (ADVANCE), seemed to vindicate the use of rosiglitazone demonstrating no adverse effects and, in some cases, lower rates of cardiovascular events. Nevertheless, the controversy surrounding the safety of TZDs as therapies for T2DM seems likely to continue, particularly given recent changes to licensing laws requiring that T2DM therapies demonstrate long-term cardiovascular benefit as well together with blood glucose-lowering effects.

In light of the difficulties surrounding PPAR γ agonists, glitazars, which activate both PPAR γ and PPAR α , are currently under investigation as T2DM therapies. These agonists aim to utilize the insulin-sensitizing properties of PPAR γ and the lipid-lowering properties of PPAR α . Two of these compounds – muraglitazar and tesaglitazar – reached phase III clinical trials before being rejected due to safety concerns. More recently, another dual PPAR agonist, aleglitazar has been reported as an effective therapy for T2DM and, importantly, has demonstrated an improved safety profile compared to TZDs.

Last Words

The question is raised as to why some nonadipose tissues express multiple PPARs, for example, PPAR γ and PPAR δ in macrophages and PPAR α and PPAR δ in muscle. Activation of all three PPARs appears to decrease systemic lipid availability

and to decrease lipid (TAG and/or cholesterol) storage in non-adipose tissue. One possibility is that each individual PPAR activates overlapping but distinct downstream metabolic pathways. Perhaps more likely, it may be that the physiological ligands (presumably upstream lipid-based messengers) for activation of each of the PPARs are unique and that such ligand distinctness allows specificity of cellular downstream metabolic responses. PPARs are, thus, jacks of all trades, and masters of (at least) one! Although their individual specific physiological roles still require much further investigation, and there is still much to be learned, it is clear that, as ligand-activated transcription factors, the PPARs represent attractive targets for the development of selective therapeutic agents for pharmacological modulation of lipid metabolism. Treating dyslipidemia and T2DM and their extensive ranges of associated complications places a massive strain on the health budget, both in Western societies and now even in the developing world where the incidence of these diseases is increasing.

Glossary

Autophagy Degradation of cytosol and organelles by protein turnover involving the yeast vacuole or the lysosome in mammals.

Biogenesis Process of assembly.

Microbodies Another name for peroxisomes and similar organelles (glyoxysomes and glycosomes).

Organelle A subcellular, membrane-enclosed compartment performing specialized functions.

Peroxisomal matrix Lumen of the peroxisome.

Peroxisome A subcellular organelle involved in many lipid metabolic pathways.

Pexophagy Peroxisome turnover by selective autophagic degradation.

Ubiquitination A highly conserved posttranslational protein modification involving covalent attachment of a 76 amino acid ubiquitin (Ub) polypeptide to the substrate.

Vacuole or lysosome Organelle in which protein turnover and recycling occurs. The organelle is called the vacuole in yeast and the lysosome in mammalian cells.

Peroxisome-Like Organelles

Peroxisomes are related to specialized organelles called glycosomes in parasites such as Trypanosomes, and to plant glyoxysomes, but are unrelated to hydrogenosomes, mitochondria, and chloroplasts. Collectively, peroxisomes, glyoxysomes, and glycosomes are also referred to as microbodies. The Woronin body (named after Russian biologist Mikhail Woronin) is a peroxisome-derived microbody found near the hyphal-dividing septum in filamentous Ascomycete fungi such as *Neurospora crassa*. This organelle with a dense core is involved in plugging of the postwound septal pores restricting cytoplasmic loss at the injury sites.

Peroxisome Origin and Distribution

Peroxisomes exist in all eukaryotes, from single- and multicellular microorganisms, to plants and animals. Unlike mitochondria, nuclei, and chloroplasts, peroxisomes have no DNA. Consequently, all their proteins are encoded by nuclear genes. Christian de Duve proposed that peroxisomes may have been the first endosymbionts (allowing the cells to withstand rising free molecular oxygen in the Earth's atmosphere) which subsequently lost their DNA. However, the evidence for an endosymbiont origin is much weaker than it is for mitochondria or chloroplasts and it now appears that they may have been formed *de novo* from the endoplasmic reticulum (ER).

Like other organelles, peroxisomes divide and segregate to distribute themselves within cells and to provide daughter cells with peroxisomes. Proper peroxisome distribution requires organelle movement on cytoskeletal (actin in plants and fungi and microtubules in mammals) filaments. Unlike nuclei and the Golgi apparatus, but similar to mitochondria or chloroplasts, peroxisome division is uncoupled from the cell cycle.

Functions of Peroxisomes

The principal function of peroxisomes is to house many metabolic pathways that are involved in various aspects of lipid metabolism. These include enzymes involved in the degradative oxidation (e.g., β -oxidation of very long-chain fatty acids, 2-methyl-branched fatty acids, dicarboxylic acids, leukotrienes, bile acid intermediates and cholesterol side chains, and both α - and β -oxidation of 3-methyl-branched-chain fatty acids); the early steps in the synthesis of either glycerolipids or plasmalogens; the formation of bile acids, dolichol, and cholesterol; the catabolism of purines, polyamines, and amino acids; and the detoxification of reactive oxygen species such as hydrogen peroxide, superoxide anions, and epoxides. In methylotrophic yeasts, peroxisomes are also involved in the metabolism of methanol and methyl amines. Glycosomes contain the glycolytic enzymes, in addition to enzymes common to most peroxisomes, whereas plant glyoxysomes have some or all of the glyoxylate pathway enzymes. Peroxisomes in the leaves of plants also participate in photorespiration.

Despite the fragility of the organelle during biochemical purification, the peroxisome membrane is impermeable to small molecules such as NAD(H), NADP(H), acetyl-CoA, and even protons *in vivo*. Consequently, it is not surprising that the peroxisomal membrane has a number of transporters for fatty acids, fatty-acyl-CoA esters, metabolites, and adenosine triphosphate (ATP).

Human Peroxisome-Related Disorders

Currently, there are about 20 peroxisomal disorders known, many of which are fatal. These diseases affect either a single metabolic enzyme or the assembly of the organelle itself (Table 1). Almost all of the genes involved in the human

Table 1 Human peroxisomal disorders involving metabolism and biogenesis

<i>Disease</i>	<i>Peroxisomal enzyme affected</i>
<i>Peroxisomal metabolic disorders</i>	
Pseudoneonatal adrenoleukodystrophy	Acyl-CoA oxidase (Acox1)
Multifunctional protein 2 (MFP2) deficiency	MFP2 involved in β -oxidation of very long chain and 2-methyl-branched fatty acids
Peroxisomal thiolase deficiency	3-Ketoacyl-CoA thiolase
X-linked adrenoleukodystrophy	ALDP (transporter)
Rhizomelic chondrodysplasia punctata Type 2	Dihydroxyacetonephosphate acyltransferase
Rhizomelic chondrodysplasia punctata Type 3	Alkyl-dihydroxyacetonephosphate synthase
Refsum's disease (Classical)	Phytanoyl-CoA hydroxylase
Glutaric aciduria Type 3	Glutaryl-CoA oxidase
Hyperoxaluria Type I	Alanine:glyoxylate aminotransferase
Acatalsaeamia	Catalase
Mevalonic aciduria	Mevalonate kinase
Di/trihydroxycholestanoic acidaemia	Trihydroxycholestanoil-CoA oxidase (Acox2)
Adult-onset sensory motor neuropathy	2-Methylacyl-CoA racemase
<i>Disease</i>	<i>Peroxisomal genes affected</i>
<i>Peroxisome biogenesis disorders</i>	
Zellweger syndrome	<i>PEX1, PEX2, PEX3, PEX5, PEX6, PEX10, PEX12, PEX13, PEX16, PEX19</i>
Neonatal adrenoleukodystrophy	Several <i>PEX</i> genes (<i>PEX1, PEX5, PEX6, PEX10, PEX12, PEX13</i>)
Infantile Refsum's disease	Several <i>PEX</i> genes (<i>PEX1, PEX2, PEX5, PEX12</i>)
Rhizomelic chondrodysplasia punctata Type I	<i>PEX7</i>
Neonatal microcephaly	<i>DLP1</i>

peroxisome biogenesis disorders (PBDs) are now known – they fall within the *PEX* genes required for peroxisome biogenesis. As many *PEX* genes are similar in yeasts and humans, a better understanding of the functions of these genes in yeast can be applied to understand human peroxisome disorders. Moreover, mouse models for human PBDs also offer the promise of better insights in understanding the symptoms of these diseases, their diagnoses, and eventual therapeutic intervention.

Biogenesis of Peroxisomes

As peroxisomes lack DNA, all their proteins must be imported from genes encoded in the nucleus. Most of the proteins that reside in the peroxisome matrix and membrane are synthesized on free ribosomes in the cytosol and then imported posttranslationally to the organelle. Typically, peroxisome biogenesis involves the formation of the peroxisomal membrane followed by the import of matrix proteins leading to

further proliferation of these organelles. Around 32 *PEX* genes, encoding proteins named peroxins, along with dynamins (and related proteins) are necessary for the biogenesis of the organelle. Most of these genes are found in multiple organisms and many are conserved in humans (Table 2). Though the general principles of biogenesis appear to be common to organisms across the evolutionary spectrum, there are indeed organism-specific variations.

Peroxisomal Matrix Protein Import

Peroxisomal matrix protein import differs from other protein translocation systems in two ways. First, fully folded proteins translocate across the peroxisomal membrane, and second, it is assumed that transient assembly of peroxisomal importomer occurs in response to the signal. Proteins destined for the peroxisome matrix have one or more peroxisome-targeting signals (PTSs). Most matrix polypeptides have a conserved, C-terminal, tripeptide PTS1 (-SKL in the one letter amino acid code, or its conserved variants). Others have an N-terminal or internal sequence termed PTS2 {(R/K)(L/V/I)X₅(H/Q)(L/A)}_n. A few proteins, such as *Saccharomyces cerevisiae* acyl-CoA oxidase, either have no canonical PTS1 sequence or have one that is dispensable, suggesting that they may possess other, as yet undefined, features that allow them to be targeted to the peroxisome lumen.

Matrix proteins synthesized in the cytosol are bound by cytosolic receptors – Pex5p in the case of PTS1, and Pex7p in the case of PTS2 (see Figure 1). These receptor-cargo complexes then move to the peroxisome membrane where they dock with protein subcomplexes that are in or on the membrane. Two such complexes are a docking subcomplex, comprised minimally of peroxins Pex8p, Pex13p, Pex14p, and Pex17p, and a really interesting new gene (RING)-protein subcomplex, consisting of three RING proteins Pex2p, Pex10p, and Pex12p (and other yeast peroxins, such as Pex3p and Pex8p). The RING proteins have a characteristic zinc-binding domain and are members of a protein family whose first member was called RING. There is evidence that the protein subcomplexes are dynamic (e.g., the docking and RING-protein subcomplexes can come together as a larger complex during import). The PTS receptors, Pex5p and Pex7p, are believed to shuttle from the cytosol to the peroxisome membrane or lumen of the organelle, where they release their cargo, before they return back to the cytosol for another round of import. This is referred to as the extended shuttle model for matrix protein import. The RING-protein subcomplex is not involved directly in the translocation of proteins into peroxisomes, but provides E3 ligase activity for ubiquitination of Pex5p and Pex20p during receptor/coreceptor recycling to the cytosol. Many other peroxins and chaperones, such as Djplp, Hsp70, and Hsp40, are implicated in matrix protein import, but their precise roles are still under investigation.

The PTS2 pathway, which is dependent on the receptor, Pex7p, requires different additional proteins depending on the organism of its origin. In *S. cerevisiae*, the redundant proteins, Pex18p and Pex21p fulfill this function, whereas in *Yarrowia lipolytica*, *Neurospora crassa*, and *Pichia pastoris*, Pex20p, the PTS2 coreceptor, is needed, and in mammals an alternatively spliced

Table 2 Proteins involved in peroxisome biogenesis*Proteins involved in the formation of preperoxisomal vesicles and peroxisomes from the ER*

Pex3p	A ~40 kDa integral PMP conserved from yeast to humans that binds Pex19p and is defective in CG12 of the PBDs. Needed for assembly/stability of the RING-domain subcomplex comprised of Pex2p, Pex10p, Pex12p in yeast. Traffics through the ER.
Pex16p	A ~45-kDa integral PMP found in <i>Y. lipolytica</i> that binds Pex19p and is defective in CG9 of the PBDs. Traffics through the ER. Facilitates import of some peroxisomal proteins such as catalase and thiolase. Inhibits peroxisome division. No homolog found in <i>S. cerevisiae</i> . More common in higher eukaryotes.
Pex19p	A ~33-kDa farnesylated protein of yeasts and humans. Predominantly, cytoplasmic/partly peroxisomal. Chaperone and import factor for newly synthesized, class I integral PMPs. Recognizes some, but not all, mPTSs. It is defective in CG14 of the PBDs.

Proteins involved in matrix protein import

Pex1p	A ~100–150 kDa ATPase (AAA family) conserved from yeast to humans. Interacts with Pex6p and other peroxins. Involved in PTS receptor recycling from the peroxisome membrane to the cytosol during import. Defects in Pex1p are the most common cause of the PBDs (CG1).
Pex2p	A ~40-kDa integral PMP with a carboxy-terminal, cytoplasmically-exposed, zinc-binding RING domain. Has been identified in yeasts and humans, interacts with Pex3p, Pex10p, and Pex12p. Has E3 ligase function for Ubc4-dependent polyubiquitination of Pex5p during receptor recycling. Defective in CG10 of the PBDs.
Pex4p	A ~20–24 kDa peroxisome-associated ubiquitin-conjugating enzyme that interacts with Pex22p. Has been identified in several yeast species, but not in any metazoan. Involved in mono-ubiquitination of Pex5p.
Pex5p	A ~70-kDa, predominantly cytoplasmic/partly peroxisomal protein that is conserved from yeast to humans. It is the PTS1 receptor and has a PTS1-binding domain in its carboxy-terminal half. It interacts with several peroxins (Pex7p, Pex8p, Pex10p, Pex12p, Pex13p, and Pex14p) and is defective in CG2 of the PBDs. In yeast, it is monoubiquitinated by Pex4p during receptor recycling and polyubiquitinated by Ubc4/Ubc5 in a quality-control step.
Pex6p	A ~100-kDa (AAA family) ATPase conserved from yeast to humans. Interacts with Pex1p and is involved in PTS receptor recycling from the peroxisome membrane to the cytosol during import. Defective in CG4 of the PBDs.
Pex7p	A ~40-kDa, WD40-repeat-containing protein that is the PTS2 receptor. Defective in CG11 of the PBDs.
Pex8p	A variably sized (60–80 kDa), peripheral, but intraperoxisomal protein that interacts with Pex5p and the docking subcomplex; found only in fungi. It is an intraperoxisomal organizer of the peroxisomal import machinery in <i>S. cerevisiae</i> but not in <i>P. pastoris</i> . It plays a weak role in cargo release <i>in vitro</i> .
Pex9p	A ~44-kDa integral PMP found only in the yeast <i>Y. lipolytica</i> .
Pex10p	A ~35-kDa integral PMP with a carboxy-terminal, cytoplasmically exposed, zinc-binding RING domain. Conserved from yeast to humans, interacts with Pex2p, Pex3p, Pex5p, and Pex12p, and is defective in CG7 of the PBDs.
Pex12p	A ~40-kDa integral PMP with a carboxy-terminal, cytoplasmically exposed, zinc-binding RING domain. Conserved from yeast to humans, interacts with Pex3p, Pex10p, and Pex12p and is defective in CG10 of the PBDs. Has E3 ligase function for Pex4p-dependent monoubiquitination of Pex5p during receptor recycling.
Pex13p	A ~44-kDa integral PMP with a carboxy-terminal, cytoplasmically exposed SH3 domain. Conserved from yeast to humans, interacts with Pex5p and Pex14p, and is defective in CG13 of the PBDs.
Pex14p	A ~40-kDa PMP conserved from yeast to humans that interacts with Pex5p, Pex8p, Pex13p, and Pex17p. Proposed to be part of the minimal translocon for import of PTS1 proteins, along with Pex5p.
Pex15p	A ~44-kDa integral, tail-anchored PMP identified only in <i>S. cerevisiae</i> . Interacts with Pex6p.
Pex17p	A ~25-kDa integral PMP that interacts with Pex14p. Has been identified only in fungi.
Pex18p	A ~31-kDa soluble protein involved only in PTS2-protein import. It is highly similar to Pex21p, and acts as a PTS2 co-receptor. Identified only in <i>S. cerevisiae</i> .
Pex20p	A ~46-kDa soluble protein involved only in PTS2-protein import. Identified only in some fungi that use this protein as a PTS2 coreceptor instead of Pex18p/Pex21p in <i>S. cerevisiae</i> .
Pex21p	A ~31-kDa soluble protein involved only in PTS2-protein import, is highly similar to Pex18p, and might act as a PTS2 coreceptor. Identified only in <i>S. cerevisiae</i> .
Pex22p	A ~20-kDa integral PMP of yeasts that interacts with Pex4p and anchors it on the peroxisomal membrane.
Pex23p	A ~46-kDa integral PMP. Identified only in <i>Y. lipolytica</i> .
Pex24p	A ~61-kDa integral PMP found in yeasts; required for the proper localization of some, but not all, PMPs and matrix proteins.
Pex26p	A ~34-kDa integral PMP found in higher eukaryotes. Anchors Pex1p and Pex6p to peroxisomal membrane forming heteromeric AAA ATPase complexes required for import. Defective in PBD patients (CG8).

Proteins involved in controlling peroxisome size and number

Pex11p	A ~25-kDa integral PMP required for normal peroxisome abundance and division. Many species contain several <i>PEX11</i> genes.
Pex25p	A ~45-kDa <i>S. cerevisiae</i> PMP that regulates peroxisome size and number.
Pex27p	A ~44-kDa peripheral <i>S. cerevisiae</i> PMP that regulates peroxisome size and number. Interacts with Pex25p.
Pex28p	A ~66-kDa integral PMP of yeasts that regulates peroxisome size, number, and distribution. Acts at steps upstream of Pex30p, Pex31p, and Pex32p.
Pex29p	A ~63-kDa integral PMP of yeasts that regulates peroxisome size, number, and distribution. Acts at steps upstream of Pex30p, Pex31p, and Pex32p.
Pex30p/31p/32p	Dysferlin domain containing PMPs of yeasts that regulate peroxisome size, number, and distribution. Partially redundant with each other. Acts at steps downstream of Pex28p and Pex29p.

(Continued)

Table 2 (Continued)

Vps1p/Dnm1p	Dynamin-related proteins (DRPs) and GTPases required for fission and actin cytoskeleton organization. Vps1p/Dnm1p found in yeasts while DLP1 is a homolog found in mammals. A patient has been described with a heterozygous, dominant-negative mutation in DLP1.
Mdv1p/Caf4p	Conserved, WD repeats-containing adaptor proteins required for DRP recruitment in yeasts. Interacts with Dnm1p/Vps1p and Fis1p.
Fis1p	A ~18-kDa conserved, TPR repeat-containing protein required for localization of Mdv1p/Caf4p and DRPs.
Rho1p	A ~23-kDa conserved GTPase belonging to Ras-like protein subfamily, involved in actin assembly on peroxisomes. Interacts with Pex25p and Pex30p in yeast.
<i>Proteins involved in peroxisome inheritance</i>	
Inp1p	A ~47-kDa fungal PMP involved in retention of peroxisomes in mother and daughter cells.
Inp2p	A ~81-kDa fungal PMP involved in peroxisome movement through interaction with myosin class V motor, Myo2p.
Myo2p	A ~180-kDa protein that is an actin-based motor that propels peroxisome movement.

CG, complementation group; SH3, Src-homology; PMP, peroxisomal membrane protein.

Note: Molecular weights of the proteins are those of *S. cerevisiae* unless mentioned otherwise.

Figure 1 Overview of the peroxisomal matrix protein import cascade. Protein import occurs in four steps as outlined: (1) recognition of PTS-containing (cargo) proteins by the import receptors (Pex5p for PTS1 and Pex7p/coreceptor for PTS2) in the cytosol followed by delivery of the receptor–cargo complexes to the peroxisomal membrane; (2) translocation of the complex to the peroxisome lumen through a translocon formed by the docking (Pex13p, Pex14p, Pex17p, and Pex8p) subcomplex, which associates with the RING (Pex2p, Pex10p, and Pex12p) subcomplex peroxins; (3) delivery of the cargo by disassembly of the receptor–cargo complex to the peroxisomal lumen; and (4) receptor recycling back to the cytosol. The PTS1 receptor Pex5p, and the PTS2 coreceptor, Pex20p, (not shown) are monoubiquitinated by Pex4p or polyubiquitinated by Ubc4/Ubc5. AAA peroxins Pex1p and Pex6p (anchored to membrane by Pex15/Pex26p) dislocate monoubiquitinated Pex5p and Pex20p from the membrane and recycle them back to cytosol for further rounds of import. During this process, Pex5p and Pex20p are deubiquitinated. Polyubiquitinated Pex5p and Pex20p are degraded by the 26S proteasome. Numbers indicate the corresponding Pex proteins. Ub indicates ubiquitination.

form of Pex5 (Pex5L) is necessary for PTS2 import. However, the docking and RING-proteins are required in common for both PTS1 and PTS2 import pathways, leading to the current view that a common translocation machinery is involved for both these pathways.

Examples of organism-specific variations in the general scheme of biogenesis include the apparent lack of the entire PTS2 pathway (PTS2 proteins and Pex7p, the PTS2 receptor) in worms (*Caenorhabditis elegans*), and the dependence of the PTS2 import pathway on the PTS1 receptor, Pex5, in

mammals, but not in yeasts. However, even where such differences exist, the underlying molecular mechanism is similar. This is illustrated by the point that the proteins Pex18p and Pex21p from *S. cerevisiae*, Pex20p from *Y. lipolytica*, and Pex5L in mammals all have a conserved motif that allows them to interact with Pex7p and/or PTS2 cargo to facilitate the PTS2 import pathway.

The import receptors are released from the peroxisomal membrane back to the cytosol for another round of import at the end of receptor cycle. The PTS1 receptor (Pex5p) and the PTS2 coreceptor (Pex20p) undergo monoubiquitination by a

peroxisome-associated ubiquitin-conjugating enzyme, Pex4p, before they are recycled back to the cytosol from the peroxisome membrane. This receptor-recycling step requires Pex4p, its peroxisomal membrane anchor Pex22p, the RING sub-complex proteins as E3 ligases for PTS receptor/coreceptor ubiquitination and the AAA ATPases, Pex1p and Pex6p. In the absence of any component of the receptor recycling machinery (Pex1p, Pex4p, Pex6p, and Pex22p), Pex5p and Pex20p are polyubiquitinated and degraded by the proteasome, as part of a quality-control step.

Unlike the transport of unfolded proteins into other organelles such as the ER and mitochondria, folded and oligomeric proteins can be transported across the peroxisomal membrane. How such large multisubunit complexes are transported across the membrane is unknown, but the translocon in the peroxisomal membrane may be assembled transiently, using primarily the PTS receptors and Pex14p. Other proteins associated with Pex14p may improve the efficiency of protein translocation across the peroxisome membrane in unknown ways.

Import of Peroxisomal Membrane Proteins

In yeast, peroxisomal membrane protein (PMP) import requires the peroxisomal integral membrane protein, Pex3p, and Pex19p, a soluble factor that docks with it. Yeast mutants lacking either of the two peroxins fail to form peroxisomes. PMPs have one or more sequences (mPTSs) that direct them to the peroxisomal membrane with the correct topology. Although a dozen or so mPTSs have been defined in several yeast and mammalian PMPs, they have no simple consensus sequence. However, most of these PMPs bind Pex19p, a chaperone and import factor for PMPs. Recent findings suggest that the PMPs undergo anterograde transport via the ER to peroxisomes. Many peroxins (e.g., Pex3p, Pex16p, and Pex30p) are transported in this fashion. It has been postulated that these PMPs concentrate on ER and then migrate to peroxisome via ER-derived vesicles that then fuse with membranes of preexisting peroxisomes to allow growth.

Most mutants affecting the import of either peroxisomal matrix or membrane proteins have organelle remnants, in some but perhaps not all, organisms.

Regulation of Peroxisome Number, Volume, and Contents

In response to environmental signals, cells regulate peroxisome number, volume, and contents, allowing them to respond to various factors such as environmental or metabolic stresses, cell division, segregational imbalances, removal of damaged peroxisomes, and developmental reprogramming. Various pathways govern the control of peroxisome number and size. The first pathway is peroxisome division, in which a preexisting peroxisome divides by fission, regulating peroxisome number incrementally. The second pathway is 'peroxisome proliferation', in which the induction of peroxisomes leads to many new organelles. This pathway allows a rapid increase of organelle number as compared to division. The final pathway is 'peroxisome turnover', during which peroxisome numbers are

controlled by general (autophagic) or specific (pexophagic) processes.

Peroxisomes can be induced to proliferate in many organisms in response to metabolic needs. Examples include the induction of proliferation of hepatic peroxisomes by fibrates drugs, phthalate plasticizers, and xenobiotics, or the induction of peroxisomes in the methylotrophic yeast, *Pichia pastoris*, by methanol or oleate. The contents of the organelle are also responsive to the environment, as illustrated by the fact that peroxisomes of yeasts grown on oleate have induced levels of the fatty-acid β -oxidation enzymes, whereas methylotrophic yeasts grown on methanol have elevated levels of alcohol oxidase and dihydroxyacetone synthase. Peroxisome volume can also be regulated by proteins such as Pex11p, Pex25p, and Pex27p–32p and various dynamin-related proteins.

Excess peroxisomes can be turned over by autophagic mechanisms involving the lysosome in mammals, or its yeast equivalent, the vacuole.

Division and Proliferation of Peroxisomes

The division of peroxisomes is compatible with two models. The first model proposes that peroxisomes arise by budding and fission from preexisting peroxisomes, and may be the one that is used in normal, mitotically dividing cells. The other model is that peroxisomes arise either *de novo* or from some other reservoir of membranes such as the ER. Mature peroxisomes are then generated from this membrane reservoir via a variety of biogenesis intermediates. This model may be more applicable to the proliferating peroxisomes and to the regeneration of peroxisomes in *pex* mutants complemented by the affected gene. Peroxisome division is initiated by the signal from within. In *Yarrowia lipolytica*, the signal for the initiation of division is generated either by remodeling of peroxisomal membrane lipids or via metabolites generated by peroxisomal fatty-acid β -oxidation. Proteins involved in peroxisome division and inheritance to daughter cells (in yeast) are shown in Table 2.

Glossary

Degenerate codon A three-nucleotide (triplet) sequence encoding more than one amino acid, realized by synthesis of a pool of triplets having more than one nucleotide at one or more positions, or by the combination of a pre-synthesized set of triplet codons that may be used as a block for further synthesis. Degenerate codons may be represented in shorthand according to standard abbreviations, for example, reactive nitrogen species for (adenosine (A) or guanosine (G)) followed by (A, G, cytidine (C), or thymidine (T)), followed by (G or C).

Elution Process of dissociation which causes the dissociation of bound phage from an immobilized target molecule, for example, using low pH or chaotropic agents.

Enrichment Process by which peptide or protein variants with specific binding properties are amplified from a diverse library. An enrichment ratio of the number of phage eluted

from an immobilized target divided by the number eluted from a control is often used to measure enrichment.

Enzyme-linked immunosorbent assay (ELISA) An assay for binding affinity, typically in which a target molecule is coated onto a plastic plate, a second molecule (the analyte) is added, and a third molecule is used to detect binding of the analyte.

Helper phage A bacteriophage which supplies the necessary gene products for packaging of a phagemid construct and is usually deficient in packaging itself into virions.

Panning Process of selecting phage for binding to a target protein, especially when the target is coated onto an immunosorbent plastic plate.

Phagemid A DNA vector constructed from the combination of replication and other genetic elements from a plasmid with replication, packaging, and other genetic elements from the genome of a bacteriophage.

Applications of Phage Display

Phage display has found many applications in the discovery, engineering, and analysis of peptides and proteins including (1) discovery of novel peptide mimotopes and antibodies for binding to proteins and other targets, (2) optimization, affinity maturation, or mutagenic scanning of antibodies and other proteins for reagent or therapeutic use, (3) identification of specific peptide substrates for proteases and other enzymes, and (4) preparation of specific nanoparticle materials. In short, it is an effective means of producing billions of mutated protein variants and selecting from the pool those variants with specific binding properties. Typically, filamentous phage such as Fd, M13, and related phages that infect *Escherichia coli* bacteria are used as vectors for phage display of peptide or protein diversity libraries; however, other species such as T7 phage may be used.

Phage display has contributed in the protein engineering stages of development of biological therapeutics such as pegvisomant (Somavert® hGH (human growth hormone) antagonist), adalimumab (Humira® anti-tumor-necrosis-factor (TNF) α monoclonal antibody), ranibizumab (Lucentis® anti-vascular-endothelial-growth-factor (VEGF) monoclonal antibody Fab), romiplostim (Nplate® thrombopoietin-receptor agonist peptibody), and motivizumab (anti-RSV (respiratory syncytial virus) monoclonal antibody). Many more biotherapeutics appear to be in the pipeline as a result of more extensive application of the technology to antibodies and other proteins. In addition, phage particles themselves, having been selected for specific binding properties, have found application as nanoparticles in novel materials-science applications, including the production of phage-based lithium batteries.

Phage Display Vectors

Phage display is a rapid means for discovery of novel peptides and proteins from large libraries of genetically engineered variants. The process begins with construction of a phage or phagemid vector that encodes either an initial protein scaffold or a random-sequence peptide as a fusion protein with a phage coat protein. Typical constructs involve a promoter region driving expression of the fusion protein in which a secretion signal sequence (SS) is followed by the display gene and all or part of a phage coat protein, for example, g3p or g8p (proteins encoded by gene-3 or gene-8 of bacteriophage M13). Alternatively, with appropriate modifications, the displayed protein may be fused at the C-terminus of the coat protein or it may be linked to a modified phage protein through formation of a specific disulfide bond. Filamentous phage(mids) are particularly useful vectors because their structure readily adapts to accommodate the size of DNA packaged into the virion.

Polyvalent and Monovalent Phage Display

When many copies of a fusion protein are displayed on each virion, each particle may simultaneously bind to several molecules of a surface-immobilized target. In this format, called polyvalent display, even intrinsically weakly binding variants appear to bind tightly because of the avidity effect. As this effect can mask tighter binding (higher intrinsic affinity) interactions, constructs that limit the display of the fusion protein to yield virions that usually display not more than one copy were developed. This format, called 'monovalent display', facilitates stringent selections for very high-affinity interactions. Statistically, monovalent display vectors allow for display of multiple

copies of the fusion protein by a small fraction of the virion population, but the difference between monovalent and polyvalent formats can be dramatic in terms of avidity effects. The two formats have been exploited to: (1) identify novel, low-affinity binding peptides in a polyvalent system, followed by (2) affinity maturation of the low-affinity peptides through construction of secondary libraries and selection in a monovalent system.

Phage Vectors

Phage vectors consist of an essentially complete phage genome, often M13 phage, into which is inserted DNA encoding the protein or peptide of interest (Figure 1). Typically, the remainder of the phage genome is left unchanged and provides the other gene products needed for the phage life cycle. For facile growth and propagation of phage in *E. coli*, the function of the fusion protein in the life cycle of the phage must be maintained, and this places constraints on the types of fusions that are usually produced using phage vectors. For example, large proteins may be poorly displayed and/or may interfere with phage packaging or infection.

Phagemid Vectors

Phagemid vectors consist of a typical plasmid construct into which a phage origin of replication (ORI), including the phage-packaging region of DNA from the phage genome, and a gene for the displayed fusion protein have been inserted (Figure 1). In this case, the phagemid DNA can be replicated independently of phage production for mutagenesis and amplification. However, for phage display of the protein, the remaining phage gene functions must be supplied by another construct, usually a helper phage, which is packaged into virions with lower efficiency than the phagemid itself. When

E. coli cells transfected with the phagemid, grown under selective pressure with an appropriate antibiotic, are infected with helper phage at an appropriate multiplicity of infection (MOI), both constructs undergo replication, but mature virions predominantly contain phagemid rather than helper-phage DNA. However, both types of particles can display the fusion protein; thus, antibiotic selection of cells containing the desired phagemid is needed. These examples indicate the most commonly used types of phage and phagemid vectors; however, other monovalent and polyvalent displaying phage and phagemid constructs utilizing several different phage coat proteins have also been described.

Phage Libraries

A phage library may begin with a wild-type protein expressed in a phage(mid) system or with a phage(mid) vector, into which DNA-encoding completely novel peptides have been inserted.

Construction of Libraries

The generation of sequence diversity in a phage-display library is usually accomplished by typical site-directed mutagenesis techniques, such as oligo-directed single-stranded template mutagenesis, polymerase chain reaction (PCR) mutagenesis, or cassette mutagenesis using restriction enzymes and DNA ligase to cut out a segment of DNA and replace it with a synthetic piece. Highly diverse DNA sequences can be generated using standard solid-phase deoxynucleotide synthesis techniques in which individual nucleotides are randomized by adding to the growing polynucleotide chain a mixture (which may be equimolar or of a biased, specified composition) of all four nucleotides, or a subset of adenosine (A),

Figure 1 Construction of phagemid and phage vectors. Phagemid and phage DNA constructs are shown with appropriate origins of replication (ori), a gene for the protein of interest (shaded) fused the gene-3 or gene-8 encoded coat proteins of filamentous M13 phage and preceded by a secretion-signal sequence, as well as a gene for antibiotic resistance. The remaining genes of the phage vector or helper phage encode other proteins. The DNA is packaged as a single strand in the virion (shown in cartoon form) with many copies of the g8 protein along the length of the particle, a few copies of the g3 protein (two-lobe structure) at one end, and other structural proteins (not shown). The g3p or g8p fusion proteins are shown as filled triangles attached to the corresponding coat protein. In monovalent phage display, expression of the fusion is statistically limited so that very few particles contain more than one copy of the fusion protein, while in polyvalent display, a range of fusion-protein densities is possible.

guanosine (G), cytidine (C), or thymidine (T), rather than a single nucleotide (Table 1). The degeneracy of the genetic code makes possible the generation of chemically related subsets of codons depending on the amino acids encoded, or specific codons may be chosen using triplet codon synthesis to construct the oligonucleotides (Table 2). In some cases, the use of very small codon subsets encoding two to four amino acids have been useful for the generation of diversity libraries yielding novel binding properties or enhanced binding affinities. Once oligonucleotides with appropriate diversity have been designed and synthesized, mutagenesis is carried out with the phage or phagemid vector on an appropriate scale to yield a sufficient number of DNA molecules (moles of product) to represent the desired diversity as described below. The mutagenesis products are transformed into *E. coli* and propagated in culture (along with helper phage in the case of phagemid vectors) to yield a library of peptide- or protein-displaying phage particles.

Design of Diversity Libraries

The key consideration in the design of diversity libraries is the combinatorial complexity of the DNA and protein variants resulting from incorporation of random nucleotides at a given number of sites. For display of a complementary DNA (cDNA) library of genes derived from natural sources, the complexity of the library is determined by the complexity of the RNA source. For synthetic diversity libraries, the level of complexity can be specified according to the purpose of the experiment. For example, using neocarzinostatin naphthoate synthase (NNS) codon degeneracy (Table 2), all 20 commonly used L-amino acids are encoded by 32 codons. With one NNS codon randomized in this way, the library has a theoretical diversity of 32 at the DNA level and 20 at the protein level. However, this complexity grows quickly as a larger number of mutagenesis sites, n , are simultaneously randomized. For example, with 32 codons and $n = 6$ amino-acid positions, the theoretical DNA diversity is about 1.1×10^9 while the protein diversity is about 6.4×10^7 . Protein sequence diversity across additional sites can be increased by using 20 synthetic

triplet codons to encode the 20 amino acids; in this case, with $n = 7$ sites, both DNA and protein diversity would be about 1.3×10^9 . The experimentally obtained complexity or diversity of the library is limited to the number of DNA molecules that can be produced at the synthesis and mutagenesis stage, subsequently transformed into *E. coli*, and packaged into a solution of phage(mid) particles. Therefore, the number of randomized codons or the diversity of the degenerate codons may be restricted in order to obtain libraries that completely represent the designed diversity. At the virion level, phage particles are only soluble to a level of $\sim 10^{14}$ particles ml^{-1} (10^{17} l^{-1} ; or 170 nM), presenting an ultimate practical limitation for phage libraries to be produced and used at the laboratory scale. Additional limitations are imposed by the process of transformation of the phage or phagemid construct into *E. coli*, so that libraries are more commonly on the order of 10^9 to 10^{11} as measured by the total number of bacterial transformants obtained after mutagenesis and transformation using electroporation or other techniques.

Phage-Binding Selections

Phage libraries yield useful and interesting variants through a process of selection and amplification analogous to affinity-based protein purification (Figure 2).

Preparation of Packaged Virions

Once the products of random mutagenesis have been transformed into *E. coli*, phage amplification occurs through propagation of the infected culture, which in the case of phagemid libraries also includes a helper phage. Since filamentous phage particles are not lytic, large numbers of phage particles are produced during a few hours of culture growth. As the displayed protein is secreted, it is incorporated into the coat of the virion. Once a large number of phage have been produced, they are separated from the *E. coli* host by centrifugation and are often further purified using a series of precipitation and resuspension steps. The final phage stock is a solution of phage particles that are ready for appropriate binding selections.

Phage Binding and Elution

Early phage-binding selections used a simple process for separating variant protein phage that bind to a target molecule from those that do not bind. The target molecule was coated directly onto immunosorbent plastic plates or affixed to chemically activated resins. A variation on this technique involves binding of phage to a labeled target, such as a biotinylated protein, in solution, then capturing the bound phage through use of an affinity matrix that binds to the labeled target. Thereafter, the phage library is allowed to bind to the immobilized target and then removed. Nonbinding and weakly binding phage variants are washed away and the remaining tightly bound variants are eluted using affinity-selective reagents (e.g., a competing protein), mild to severe chaotropic agents, ranging from high/low pH buffers to urea, or site-specific proteases. Following elution, phage can be amplified by infecting fresh *E. coli* cells, and the

TTT	Phe (F)						X

The 64 possible triplets are shown, along with the corresponding encoded amino acids in the first two columns. The remaining columns show examples of degenerate codons (see [Table 1](#)) encoding all amino acids with 32 triplets (NNS), and other selected sets that vary in amino acid composition, including an example of a synthetic triplet codon set (*), whereby a specific set of 20 codons are used to encode 20 amino acids. Often a *supE* strain of *E. coli* is used for phage propagation, in which case the amber stop codon (**) is translated as Gln (Q).

Figure 2 Affinity-selection process for binding to an immobilized target protein using a monovalent phagemid vector. One round of binding selection or panning is shown. A population of phage particles, each displaying a different peptide or protein variant, is allowed to bind to an immobilized target. After low-affinity variants are washed away, high-affinity variants are eluted and propagated to produce an enriched pool of high-affinity variants, which may be subjected to further rounds of selection.

resulting population again subjected to binding selection. This cycle is typically repeated for several rounds, followed by analysis of selectants through DNA sequencing, which may yield nonrandom occurrences of amino acids at particular positions (i.e., a consensus sequence), or through direct binding analysis as described later. As in enzyme-linked immunosorbent assay (ELISA) experiments, nonspecific binding leads to artifacts in phage display and can be reduced using proteins or detergents that block these typically low-affinity interactions. However, large diversity libraries sometimes contain peptides that can bind to the blocking agent itself. An enrichment ratio, representing the number of phage binding to the intended target versus the number binding to the matrix or blocking agent, is often used to monitor specificity during multiple rounds of binding selection.

Phage-Binding Analysis

The individual clones selected through phage display are often further analyzed in the form of the recombinant phage particles. Beyond its use in selecting relatively rare protein variants with specific binding properties from diversity libraries of

Figure 3 Binding assays using phage display. Binding of phage-displayed protein variants is analyzed as in a typical ELISA experiment, with binding of phage to an immobilized target followed by detection with an antiphage antibody conjugated to an appropriate enzyme such as horseradish peroxidase. Relative amounts of bound phage are measured by the amount of color produced when an appropriate substrate is added.

millions to tens of billions of combinatorial variants, phage display is also used to analyze protein–protein-binding interactions without the need to separately purify large numbers of protein variants. For example, to map the binding site on a phage displayed protein for a target protein, the target protein may be coated on an ELISA plate and mutants or libraries of mutants constructed for phage display. In the case of point-mutation analysis, a phage stock of each mutant is prepared and titrated as in a typical protein-binding ELISA ([Figure 3](#)). Alternatively, using libraries of protein variants, the outcome of sequencing many selected variants may be analyzed to determine statistically which amino acids are preferred or disallowed at multiple positions in the protein while maintaining the protein's function. The utility of phage display has been demonstrated using many systems in which the results of phage selections and binding analysis have been translated into functional proteins or peptides whose biochemical properties correspond closely to their phage-displayed forms.

Glossary

Axenic In biology, axenic describes a culture in which an organism is grown in the absence of any other contaminating organisms.

Phagolysosome A membrane-bound organelle that is formed when the phagosome fuses with a lysosome. After fusion the contents within the phagosome are digested with the enzymes contained within the lysosome.

Phosphoinositol A negatively charged phospholipid that is located within the cytoplasmic leaflet of the plasma membrane. The inositol ring can be phosphorylated on the 3-OH, 4'-OH, and 5'-OH groups.

Wortmannin A furanosteroid metabolite from the fungi *Talaromyces (Penicillium) wortmannii*, which is a covalent inhibitor of phosphoinositide 3 kinases and has been shown to also inhibit phosphoinositide 4 kinases.

Introduction

Eukaryotic cells are separated from the external environment by a semi-permeable phospholipid bilayer, called the cell, or plasma, membrane. Water and certain ions pass freely across the selectively permeable cell membrane. However, a process involving membrane invagination and subsequent engulfment and formation of internal endocytic membrane vesicles is required to internalize larger macromolecules. This process, termed 'endocytosis', involves restructuring and mobilizing large amounts of lipids and phospholipids, polymerizing actin, and redistributing membrane proteins to form and transport the endocytic membrane vesicles. There are two classes of endocytosis: phagocytosis and pinocytosis. Phagocytosis (equivalent to the cell eating) is the substrate-induced internalization of macromolecules from the external environment. Professional phagocytes, such as the social amoeba *Dictyostelium discoideum*, and mammalian macrophages, neutrophils, and dendritic cells ingest particles as small as a single molecule, and up to the size of filamentous bacteria and yeast cells. Pinocytosis (cell drinking) is the internalization of external liquid and solutes. There are two types of pinocytosis: the first type (macropinocytosis) engulfs macromolecules varying from 0.2 to 10 μm in diameter and the second (micropinocytosis) engulfs macromolecules and particles less than 0.2 μm in diameter. Micropinocytosis engulfs macromolecules through small vesicles that form from regulated curvature of the membrane and assembly of scaffolding proteins such as clathrin and caveolin. Macropinocytosis and micropinocytosis will not be covered in this article. The reader is referred to previously published reviews listed in the further reading section.

Endocytosis is an extraordinarily robust and dynamic cellular process. Amazingly, *D. discoideum* cells internalize via endocytosis an amount of membrane equal to their entire surface area every 45 min, macrophages every 30 min, and fibroblasts every 2 h. Endocytosis occurs randomly all over the cell surface during macropinocytosis and locally by substrate-induced phagocytosis. Therefore, phagocytosis normally requires a receptor to recognize the substrate to be engulfed, whereas macropinocytosis is the indiscriminate gulping of fluid into the cell and is receptor independent. A common structure involved in these processes

is a concave, cup-shaped membrane invagination that involves actin and other membrane-associated proteins on the cytosolic side of the cup, which later become the phagosome or macropinosome. This article focuses on the signaling and feedback mechanisms of the formation of the phagosome.

Phagocytosis is an essential process for the innate immune/inflammatory response as white blood cells dispose of foreign invaders. Macrophages also use this process in their garbage-collecting mission as they engulf senescent or apoptotic cells and cell debris. Phagocytosis is also essential for nonaxenic *D. discoideum* to feed and survive in nature. Much of our understanding of phagocytosis has been elucidated from these amoebae and from mammalian macrophages, neutrophils, and dendritic cells. As such, a significant portion of this article is devoted to studies performed on these cell types. Phagocytosis consists of multiple stages: (1) substrate binding to the cell surface through a transmembrane receptor or possibly attachment to cell-surface adhesion proteins, (2) activation of a signaling cascade that leads to the spatiotemporal modulation of F-actin polymerization, (3) actin-dependent pseudopod extension to facilitate the engulfment and internalization of the particle followed by vesicle trafficking from endolysosomal compartments (Figure 1), and (4) subsequent removal of the actin coat from the internalized phagosome and fusion and fission to form the mature phagolysosome. The phagolysosome is the result of the fusion of the phagosome with a lysosome in which the lysosomal enzymes are released and other lytic compounds are activated to digest the phagocytosed particle.

Receptor Recognition of Particles for Engulfment in Mammalian Systems

The first stage of phagocytosis involves receptor recognition of a particle. While the surface receptor that stimulates phagocytosis has not yet been identified in *D. discoideum*, in mammalian cells several surface receptors have been studied. In these cells, the most well-known phagocytic stimulating receptor is the Fc receptor (FcR). The FcR binds to the Fc domain of immunoglobulins such as immunoglobulin G (IgG). During FcR-mediated phagocytosis, the internalized

phagosomes form by a receptor-mediated, zipper-like, progression of the membrane and cytoskeleton over the particle. Initially, IgG coats the particle and binds the FcR on the phagocytic cell. The binding of the IgG with the FcR causes a conformational change in the receptor, which initiates a signaling cascade that activates actin polymerization and progression of the membrane over the particle. This advancement of actin and membrane over the particle results in more FcRs binding other IgG molecules. This elicits a further response, which continues the advancement of the actin and membrane over the particle. The locally modulated activation of the actin via IgG-bound FcR results in the phagosome taking on the shape of the particle they ingest.

Figure 1 Phagocytic cup formation, extension and engulfment of a particle in a macrophage. The first steps (steps 1 and 2) of phagocytosis involve binding of the substrate or particle and the formation of the phagocytic cup. The extension of the phagocytic cup (step 3) involves the coordinated functions of receptors, actin, myosins, and membrane dynamics (A, B, C, and D). As the phagosome reaches closure (step 4) the particle is beginning to be internalized. Finally, the phagosome is formed and the particle is completely engulfed and internalized (step 5). At this point, the receptors and membrane are recycled and the actin and myosins dissociate from the phagosome. Involvement of Actin, Actin-Binding, and Actin-Regulating Proteins in Phagocytosis

Mammalian and *D. discoideum* cells enrich actin-polymerizing proteins (Wiskott–Aldrich syndrome protein (WASP), suppressor of cAMP receptor/WASP-family verprolin homologous protein (Scar/WAVE), and Arp2/3 complexes), actin cross-linking proteins (fimbrin, actin binding protein-120 (ABP120), α -actinin, etc.), actin monomer-binding proteins (profilin, cofilin, and Srv2/cyclase-associated protein (CAP)), membrane anchoring proteins (talin, comitin, ponticulin, and hisactophilin), F-actin fragmenting and capping proteins (severin and actin interacting protein-1 (Aip-1)), and contractile motor proteins (conventional and unconventional myosins) to the phagocytic cup at the onset, during, and until the particle has become totally surrounded by membrane. Interestingly, in mammalian cells, phagosomes enrich these proteins to the advancing phagocytic cup and dissipate at the base of the cup forming a belt-like structure during the progression of the phagosome (Figure 2).

In mammalian and *D. discoideum* cells, the membrane anchoring proteins such as talin are implicated in phagocytic substrate adhesion and in maintaining and modulating membrane/actin interactions throughout the cup formation and engulfment processes. Comitin also associates with endosomal vesicles and Golgi and is thought to be involved in membrane transport and turnover during phagocytosis in mammalian and *D. discoideum* cells. However, in *D. discoideum* there is no evidence that membranes from other organelles are diverted to the phagocytic cup or phagosome. It is apparent that the phagosome is predominately composed of plasma membrane lipids and proteins.

The actin cross-linking proteins Coronin and ABP-120 are involved in cross-linking multiple filaments of F-actin to form a mesh-like array. These proteins appear to play an important role in regulating the rate of phagocytosis. When either is knocked out in the *D. discoideum* cells, the rate of phagocytic cup formation and engulfment are drastically decreased.

The actin monomer-binding proteins comitin and profilin are important for actin turnover in the formation and maturation of the phagosome. Comitin positively affects phagocytosis, and profilin has an apparent negative role in phagocytosis.

Figure 2 Actin and actin-associated proteins are enriched at the phagocytic cup and dissipate as the membrane forms around the particle in erythrocytes. Simultaneous imaging of CFP-actin and YFP-PBD (p21 binding domain of PAK1) within a macrophage during phagocytosis of an IgG-coated erythrocyte. At 2.5 min, CFP-actin is enriched at the phagocytic cup and as time progresses to 6.5 min the actin seems to form a belt-like structure around the erythrocyte (white arrow). At 8.5 min the phagosome is closed and the CFP-actin has dissipated from the phagosome. Reproduced from Hoppe AD and Swanson JA (2004) Cdc42, Rac1, and Rac2 display distinct patterns of activation during phagocytosis. *Molecular Biology of the Cell* 15: 3509–3519, with permission from American Society for Cell Biology.

The interplay between the modulatory effects of these proteins provides a sufficient pool of monomeric actin for polymerizing F-actin during phagocytosis in mammalian and *D. discoideum* cells.

In mammalian and *D. discoideum* cells the actin polymerizing proteins Scar/WAVE, WASp, and Arp2/3 are essential for forming and extending the phagocytic cup around the molecule. Scar/WAVE and WASp proteins are known to bind profilin, actin, phosphoinositides, and the Arp2/3 complex. These proteins are essential signaling components that link small guanosine triphosphate (GTP)-binding proteins to the polymerization of actin. For instance, Scar/WAVE and WASp have been shown to interact with the small GTP-binding proteins Rac1 and Cdc42, both of which remodel the actin cytoskeleton. The Arp2/3 complex, on the other hand, directly regulates the polymerization of F-actin.

Regulation of Phagocytosis by Heterotrimeric and Small GTP-Binding Proteins

In *D. discoideum*, phagocytosis is primarily modulated by large heterotrimeric GTP-binding proteins and small GTP-binding proteins. Heterotrimeric G-proteins are posttranslationally modified with lipid moieties that allow them to interact with the inner leaflet of the plasma membrane. The heterotrimer also exhibits GTPase activity and interacts with serpentine transmembrane receptors. These G-protein-coupled receptors (GPCRs) interact with the three subunits in the heterotrimeric G-protein complex: the $G\alpha$ subunit, $G\beta$ subunit, and the $G\gamma$ subunit. Stimulated receptors catalyze the exchange of guanosine diphosphate (GDP) for GTP on the $G\alpha$ subunit. During this exchange process the $G\beta\gamma$ dimer separates from the $G\alpha$ monomer, and the heterotrimer dissociates. The activated GTP-loaded $G\alpha$ monomer and $G\beta\gamma$ dimer signal to various downstream signaling and effector proteins. The GTPase activity of the $G\alpha$ subunit inactivates the protein by hydrolyzing the GTP to GDP. The inactivation can be further modulated by regulator of G-protein signaling (RGS) proteins. Upon hydrolysis, the GDP-loaded $G\alpha$ monomer re-associates with a $G\beta\gamma$ dimer and the GPCR. In mammalian cells, 16 $G\alpha$ proteins, five $G\beta$ proteins, and 14 $G\gamma$ proteins have been identified, allowing a large number of potential combinations of trimeric forms to assemble. In contrast, in *D. discoideum* there are 14 $G\alpha$ proteins, one $G\beta$ protein, and one $G\gamma$ protein. Evidence supporting the involvement of the heterotrimeric G-proteins in phagocytosis was first conducted in *D. discoideum*. Disruptions of the *D. discoideum* $G\beta$ and $G\alpha 4$ genes will result in attenuation, but not abolition, of phagocytic efficiency. Therefore, the $G\beta$ subunit and the $G\alpha 4$ subunit are necessary, but not sufficient, for phagocytosis in *D. discoideum*.

The small GTP-binding proteins primarily differ from large heterotrimeric G-proteins in that they are monomeric and are smaller in molecular weight than the $G\alpha$ subunits. These small GTP-binding proteins associate with the plasma membrane by controlled covalent modification with lipid moieties. The small GTP-binding proteins are activated by guanine nucleotide exchange factors (GEFs) and are inhibited by GAP proteins (GAP, GTPase activating protein). There are several families of small GTP-binding proteins, which include the Ras family proteins (signal transduction), Rho/Rac family proteins

(cytoskeleton), Rab/Arf family proteins (vesicular trafficking), and the Ran family proteins (nuclear import/export). The focus here is on the Ras and Rho/Rac families of small GTP-binding proteins that are involved in phagocytosis.

Ras family proteins are involved in global cellular signal transduction including changes in the actin cytoskeleton. In *D. discoideum* cells, chromosomal disruption of RasS leads to a decrease in phagocytosis and macropinocytosis suggesting a role for Ras regulation in phagocytosis. In mammalian cells, overexpression of wild-type Rap1 or of a constitutively active form of Rap1 results in an increased rate of phagocytosis. Moreover, expression of a dominant negative form of Rap1 decreased the rate of internalization of the particles. This suggests an importance of Rap1 in the rate of phagocytosis of particles.

Rho/Rac family proteins are primarily involved in the regulation of actin cytoskeletal dynamics. In particular, while Rac1, RhoA, and Cdc42 in mammalian macrophages are involved in phagocytosis, in *D. discoideum* cells it is the mammalian Rac1 homologs Rac1A–C and the mammalian RhoA homologs RacC, RacB, and RacG that are important for this process. In fact, Rac1A–C and RacB in *D. discoideum* are critical for efficient phagocytosis. The constitutively active mutant forms of these proteins greatly inhibit the rate of phagocytosis and the rate of efflux of ingested markers. This suggests that these proteins negatively regulate phagocytosis and downstream processing of the phagosome. However, overexpressing RacC and expressing a constitutively active mutant of RacG increases the rate of phagocytosis. These results suggest that these proteins positively regulate phagocytosis.

The Rab/Arf family of small GTP-binding proteins has been shown to regulate vesicle trafficking within cells. In mammalian cells, studies of macrophage phagosome maturation have identified 18 Rab proteins involved in phagosome maturation and the biogenesis of the phagolysosome. Specifically, activated Rab5a is rapidly recruited transiently to nascent phagosomes. Rab7 is also recruited to the phagosome, but recruitment of Rab5a is a prerequisite for this event. The phagosomes' acquisition of Rab7 allows the phagosomes to fuse with late endosomes and lysosomes. The phosphoinositide 3 kinase (PI3K) modulates the recruitment of both of these proteins. Active Rab11 is also localized to nascent phagosomes and is required for recycling and retrieval of phagosomal content from the plasma membrane. Rab21 and 22 transiently localize to phagosomes containing latex beads similar to Rab5. The presence of Rab14 and 22 on phagosomes seems to be important for the delay of phagolysosomal biogenesis.

In *D. discoideum* cells, the Rab7 and Rab11 GTP-binding proteins are essential for early and late phagosome maturation and with exocytosis of unutilized material. Although these proteins have less of a role in the recognition of the particle and in the formation of the phagocytic cup, they are still essential for efficient phagocytosis. The production of phosphoinositide (4,5) biphosphate (PI(4,5)P₂) is also important for Rab7 localization and phagocytosis. This suggests that Rab7 may be recruited to the maturing phagosome via PI(4,5)P₂.

Regulation of Phagocytosis by Phosphoinositides and Phosphoinositide-Modifying Enzymes

Phosphoinositides such as PI(4,5)P₂ and phosphoinositide (3,4,5) phosphate (PI(3,4,5)P₃) are potent secondary messengers

Figure 3 Localization of PH-CRAC-GFP (a $\text{PI}(3,4,5)\text{P}_3$ -binding probe) during early, middle stages of *D. discoideum* phagocytosis of an FITC-labeled yeast cell. Images of shallow (1) and deep (2) phagocytic cups and newly formed (3) and early (4) phagosomes. PH-CRAC-GFP is labeled in green, the yeast particle in red, and H36 antibody is labeled in white. H36 antibody binds to the H36 transmembrane protein on the external surface of the plasma membrane. The time course shown is 10 min and the scale bar is 4 μm . Reproduced from Mercanti V, Charette SJ, Bennett N, et al. (2006) Selective membrane exclusion in phagocytic and pinocytic cups. *Journal of Cell Science* 119: 4079–4087, with permission from Company of Biologists.

and are involved in the modulation of the actin cytoskeleton and membrane trafficking in most eukaryotic cells. $\text{PI}(3,4,5)\text{P}_3$ is important for pseudopod extension around the particle where it transiently accumulates – rapidly decreasing once the particle has been completely enclosed by the membrane. Moreover, $\text{PI}(3,4,5)\text{P}_3$ accumulations are followed by an increase in $\text{PI}(3,4)\text{P}_2$, which peaks shortly after phagosome closure and dramatically decreases during the internalization process. The phosphoinositide levels within the cell are modulated by the activities of phosphoinositide kinases, phosphoinositide phosphatases, and phospholipases.

The formation of the phagocytic cup on the inner leaflet of the plasma membrane is primarily dependent on Rho/Rac and Arp2/3 complex activation and independent of PI3Ks. PI3Ks phosphorylate $\text{PI}(4,5)\text{P}_2$ on the 3 position of the inositol ring to form $\text{PI}(3,4,5)\text{P}_3$. Although PI3K activity is not required for phagocytic cup formation, it is essential for pseudopod extension around the particle and for phagosome maturation. PI3K activity can be visualized in living cells by expressing a fluorescently tagged pleckstrin homology (PH) domain containing protein that binds to $\text{PI}(3,4,5)\text{P}_3$ (Figure 3).

During phagocytosis, phosphoinositide phosphate 5 kinase (PIP5K) is displaced from phagosomal membrane and its product $\text{PI}(4,5)\text{P}_2$ is hydrolyzed. $\text{PI}(4,5)\text{P}_2$ degradation is essential for preventing actin polymerization and its elimination is essential for phagosome closure and scission. $\text{PI}(3,4,5)\text{P}_3$ production by PI3K is essential for phospholipase C (PLC) activation and recruitment to the membrane. The PH-domain of PLC- γ , a PLC isoform in mammalian cells, binds to $\text{PI}(3,4,5)\text{P}_3$ on the membrane. The anchoring of PLC to the membrane via $\text{PI}(3,4,5)\text{P}_3$ increases the local concentration of PLC on the membrane and increases PLC activity for $\text{PI}(4,5)\text{P}_2$. PLC converts $\text{PI}(4,5)\text{P}_2$ into inositol (3,4,5) phosphate (IP_3) and diacylglycerol (DAG). PI3K inhibition by Wortmannin in macrophages leads to accumulation of $\text{PI}(4,5)\text{P}_2$ and PIP5K on the membrane in the forming phagosome and eventually inhibits phagocytosis. The accumulation of surface charge on the phagosomal membrane increases the binding of PIP5K and as the $\text{PI}(4,5)\text{P}_2$ is degraded by PLC the surface charge is decreased and PIP5K dissociates from the phagosomal membrane.

Phagocytosis in macrophages is negatively regulated by the phosphoinositide phosphatases PTEN (phosphatase tensin homolog) and SHIP-1 (Src homology 2 (SH2) domain-containing inositol-5-phosphatase 1 (SHIP-1)). PTEN removes the phosphate from the 3-position on the inositol ring and SHIP-1 removes the phosphate from the 5-position on the inositol ring. The inhibition and deletion of each of the phosphatases increase the rate of phagocytosis in macrophages. Alternatively, the deletion of PTEN in *D. discoideum* cells decreases phagocytosis and a SHIP-1-like protein has no apparent effect on phagocytosis.

PLC, which converts $\text{PI}(4,5)\text{P}_2$ into inositol (3,4,5) phosphate (IP_3) and DAG, is essential for phagocytosis. IP_3 increases the levels of intracellular calcium, which is important in regulating phagocytosis in macrophages. In mammalian cells, $\text{PI}(4,5)\text{P}_2$ increases in the extended regions of the membrane engulfing the particle and, as PLC is recruited to the phagosome, DAG is increased at the base of the phagocytic cup. Also, DAG activates protein kinase C (PKC) which regulates many enzymes involved in phagosome maturation.

Phagocytosis is a highly conserved mechanism considering the evolutionary distance of *D. discoideum* and humans. Many of the molecular components are shared and serve a wide range of biological processes. These attributes make a classic eukaryotic organism such as *D. discoideum* a valuable tool in the investigation of these mechanisms.

Pheromone Receptors (Yeast)

J B Konopka, Stony Brook University, Stony Brook, NY, USA

J W Thorner, University of California, Berkeley, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Agonist A ligand that activates a receptor to evoke a signal.

G-protein-coupled receptor (GPCR) Possesses a characteristic seven-transmembrane-segment primary structure with its N-terminal end facing the extracellular milieu and its C-terminal end facing the cytosol.

Ligand A substance, such as a mating pheromone, that binds to a receptor molecule.

Mating projection A term used to describe the distinctive type of polarized morphogenesis observed in yeast treated with mating pheromone. A haploid cell with this

shape is commonly referred to as a shmoo. This structure forms the conjugation bridge that connects mating cells.

Transmembrane domain A region of a protein that spans a membrane bilayer. These domains are typically present in an ordered structure, such as an α -helix or β -sheet, which allows the polar carbonyl groups of polypeptide chains to be shielded from the hydrophobic core of the membrane bilayer. In the case of the GPCRs whose crystal structures have been determined, each of the transmembrane domains forms an α -helical structure.

Pheromone Receptors Are Necessary for Conjugation

Pheromone signaling occurs only between cells of different mating type. In *Saccharomyces cerevisiae*, there are two mating types, which are defined by the combination of pheromone and receptor they produce (Figure 1). Haploid cells of the α -mating type secrete the α -factor pheromone and express in their plasma membrane, the receptor (Ste2) for α -factor; conversely, haploids of the α -mating type produce α -factor pheromone and express at their surface the receptor (Ste3) for α -factor. The α -factor is an unmodified 13-residue peptide (major isoform is WHWLQLKPGQPMY, in the one-letter amino acid code) that is processed from a larger precursor and secreted from cells via the standard secretory pathway. By contrast, α -factor is a 12-residue lipopeptide (major isoform is YIIKGLFWDPAC) that is modified by farnesylation of the side chain and methyl esterification of the carboxyl group of its C-terminal Cys residue, and then exported from cells through the action of a dedicated adenosine triphosphate-driven transporter (Ste6). Cell-type identity is established by genes at the mating type locus (MAT) on chromosome III, which encode transcriptional regulators that control expression of the genes for the corresponding pheromones and receptors. Gene products required for signaling downstream of the receptors are identical and are expressed in both MAT α and MAT α cells. The genomes of other ascomycetes (i.e., those that pack their spores into an ascus), including the fission yeast *Schizosaccharomyces pombe* and the human pathogen *Candida albicans*, encode homologs of both Ste2 and Ste3. However, in certain basidiomycetes, including the plant rust *Ustilago maydis* and the human pathogen *Cryptococcus neoformans*, the pheromone receptors in the different mating types are all related to Ste3. Furthermore, other groups of fungi, such as many basidiomycetes (including mushrooms), have more than two and often many combinatorial possibilities for distinct mating types and, hence, correspondingly more complex regulation.

Binding of pheromone to a receptor triggers a signal transduction pathway necessary for eliciting the physiological

responses required to differentiate the cells and prepare them for mating. These responses include arrest of cell division in G1 to synchronize the cell cycles of the mating partners, and transcriptional induction of genes that specify proteins required for agglutination, specialized morphogenesis, cell fusion, and nuclear fusion. These proteins and the capacities they confer permit the cells to conjoin, fuse, and form a diploid zygote.

Pheromone Receptors Stimulate a Signal Transduction Pathway

The pheromone receptors induce mating by stimulating a G-protein-initiated signaling pathway that has been most extensively studied in *S. cerevisiae* and will, thus, serve as a model for description of similar pheromone-stimulated signaling events that are likely to occur in other organisms. Upon binding of the cognate pheromone, an activated pheromone receptor stimulates exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) in the α -subunit (Gpa1) of the coupled heterotrimeric G protein. The ensuing conformational change in GTP-bound Gpa1 dissociates its associated G $\beta\gamma$ complex (Ste4–Ste18). Gpa1 remains membrane-associated because its mature N-terminal residue (Gly2) is N-myristoylated and Cys3 is S-palmitoylated. The free G $\beta\gamma$ complex, which is also firmly anchored in the plasma membrane by both C-terminal S-farnesylation and carboxymethylation of the C-terminal Cys and S-palmitoylation of the penultimate Cys in Ste18, now exposes surfaces that are able to bind and recruit to the plasma membrane, the proteins needed for subsequent events (Figure 2). Studies on pheromone signaling in yeast helped to first establish that the G $\beta\gamma$ subunits can transduce a signal and are not just regulators of the G α subunit.

One protein that binds to G $\beta\gamma$ is Ste5, which acts as a scaffold by associating with the three protein kinases – Ste11 (MEKK or MAPKKK), Ste7 (MEK or MAPKK), and Fus3 (ERK or MAPK) – of a mitogen-activated protein kinase (MAPK)

Figure 1 Landmark events during conjugation of *S. cerevisiae*. Intercellular communication between cells of mating type **a** and cells of mating type **α** induces the indicated stages of conjugation, as described in the text.

cascade. The existence of such a cascade was first demonstrated unequivocally in *S. cerevisiae* and was critical for defining highly related kinase cascades that play widespread roles in the regulation of human cells. Phosphorylation and activation of Ste11 require the action of yet another protein kinase, Ste20. Ste20 is recruited to the membrane in two ways. The activator of Ste20, the small GTPase, Cdc42 (a protein of about 21 kDa), is tethered to the membrane because it is geranylgeranylated and carboxymethylated on its C-terminal Cys and, in its GTP-bound state, binds to the N-terminal regulatory domain of Ste20. Thus, Ste20 was the first member of the family of protein kinases known as p21-activated protein kinases (PAKs) to be recognized. In addition, Ste20 is localized specifically near the rest of the pheromone response machinery at the plasma membrane because a motif near the C terminus of Ste20 binds to Gβγ. The third component recruited to the plasma membrane by the released Gβγ complex is another scaffold protein (Far1) that carries the guanine-nucleotide exchange factor (Cdc24) that stimulates conversion of Cdc42 from its GDP to its GTP-bound state. Once activated via this phosphorylation cascade, Fus3 is released from Ste5, translocates to the nucleus, and relieves negative regulation of a transcription factor (Ste12) that is poised on the promoters of pheromone-responsive genes, thereby inducing the expression of those genes. Although GTP-bound Gpa1 may also engage downstream effector(s), these seem to make only a minor contribution to pheromone response in *S. cerevisiae*, but activated Gα subunits may play more important roles in the mating process in other fungi.

Complete sequence analysis of the *S. cerevisiae* genome, accomplished in 1996, identified all of the genes that contain potential Ste12-binding sites in their promoter regions; subsequent chromatin immunoprecipitation demonstrated that many of these promoters are indeed occupied by Ste12 before induction, and with the advent of DNA microarrays, all genes actually induced by pheromone have been identified. Not surprisingly, this set of genes includes those needed for cell-cycle arrest, agglutination, morphological changes, cell fusion, and nuclear fusion. Interestingly, many signaling components, including the pheromones and receptors, as well as additional gene products that function in adaptation (downregulation) of the response are induced as part of the highly organized intercellular interplay that occurs between mating cells. Collectively, these gene products control the spatial and temporal events of the mating process, as well as recovery from those changes if conjugation does not occur successfully (Figure 2).

Pheromone Receptors Sense Spatial Gradients

In *S. cerevisiae*, the pheromone receptors have been shown to play a key role in sensing the position of the mating partner and providing proper spatial orientation for the subsequent polarized morphogenesis that enables cells of opposite mating type to grow toward each other, thereby enhancing the probability of their encounter and subsequent fusion. The ability of a yeast cell to track a gradient of pheromone emanating from a cell of the opposite mating type requires dynamic interaction between signaling and adaptation, particularly at the level of the pheromones and receptors. For example, exposure of MATα cells to a-factor increases transcription of the α-factor genes, whereas exposure of MATa cells to α-factor induces expression of an extracellular protease that degrades α-factor in the medium. Another aspect of this interplay involves removal of ligand-bound receptors by endocytosis and their replacement by newly synthesized receptors, which are deposited at the site on the surface immediately adjacent to the partner cell (because the oriented morphogenesis mentioned above directs secretory vesicles to their destination). This behavior sustains the highest degree of receptor activation in the region nearest to the site on the surface that is exposed to the highest concentration of pheromone emanating from the closest potential partner. Such localized receptor signaling is thought to establish and then reinforce the spatial cues that stimulate properly oriented actin polymerization and other aspects of the directed morphogenesis necessary for conjugation. Interestingly, the pheromone receptors in *S. cerevisiae* also appear to contribute directly to cell identity. There are residues in the N-terminal region of Ste2 that are not required for pheromone induction of signaling events *per se*, yet are needed for a MATa cell to be efficiently recognized by a MATα cell as an appropriate partner for mating and fusion.

Pheromone Receptors Are Regulated at Several Levels

Control of pheromone receptor expression and function is key for proper intercellular communication and also for allowing cells to return to normal growth in the event that mating does not occur. These controls have been best studied for the

Figure 2 Schematic representation of the mating pheromone response pathway in *S. cerevisiae*. A diagram showing the main components involved in transmitting the pheromone signal in *MAT α* cells. A similar pathway operates in *MAT α* cells. Activated pheromone receptors stimulate the G α -subunit to release the G $\beta\gamma$ -subunits. The free G $\beta\gamma$ -subunits then recruit a scaffold protein, Ste5, to the membrane. Ste5 carries the components of a MAP kinase cascade and places them in proximity to another protein kinase, Ste20. The free G $\beta\gamma$ complex also recruits another scaffold protein, Far1, which carries the activator (Cdc24) of the small GTPase, Cdc42, which, in turn, is the activator of Ste20. Ste20 is further concentrated at these sites because its C terminus also binds to free G $\beta\gamma$ -subunits. Conjunction of these components achieved by the pheromone-dependent and receptor-initiated release of G $\beta\gamma$ results in activation of the protein kinase cascade, and ultimately stimulates the pheromone-responsive transcription factor, Ste12, in the nucleus. Activation of Cdc42 also promotes actin polymerization and other aspects of morphogenesis to promote highly polarized growth. Negative regulators of the pathway (shown in red on the left side) are also induced and constitute a negative feedback loop. Bar1 is a secreted protease that degrades α -factor in the medium. Afr1 negatively regulates receptor function. Sst2 is an RGS protein that promotes hydrolysis of the GTP bound to the G α -subunit (Gpa1). Msg5 is a phosphatase that dephosphorylates and inactivates the terminal MAPK (Fus3).

S. cerevisiae α -factor receptor (Ste2). The C-terminal cytosolic domain of Ste2 is the target for several adaptation mechanisms (and similar mechanisms are known to regulate the α -factor receptor Ste3). First, once ligand-bound, rapid phosphorylation of Ste2 within the C-terminal sequence appears to inhibit the ability of the receptor to continue to signal. The conformational change caused by pheromone binding makes the C-terminal segment of the receptor more accessible to certain protein kinases (casein kinase I family members) that are constitutive residents of the plasma membrane. Second, phosphorylation creates a determinant that leads to recognition by a ubiquitin ligase complex, which covalently attaches a single ubiquitin to each of several lysine residues (especially Lys337) in the C terminus (Figure 3). This monoubiquitination triggers recruitment of the receptor to clathrin-coated pits where it is endocytosed and removed from the cell surface. Third, genetic studies indicate that a pheromone-induced protein that localizes to the neck of the mating projection, Afr1, prevents Ste2 function, thereby helping to confine receptor signaling to the leading edge of the projection.

Other components of the pheromone-signaling pathway also undergo pheromone-induced downregulation. Indeed, synthesis of the most-significant negative regulator of pheromone

signaling, Sst2, is highly induced by the pheromone pathway. Sst2 was the first regulator of G-protein-signaling (RGS) protein to be recognized, making it an important model for understanding RGS function. In yeast, Sst2 promotes hydrolysis of the GTP bound to Gpa1, thereby deactivating G α and promoting its reassociation with G $\beta\gamma$. Interestingly, Sst2 functions in concert with Ste2. Sst2 binds via its Dishevelled/Egl-10/Pleckstrin (DEP) domains to the cytoplasmic C-terminal tail of Ste2, thereby tethering this regulator close to its substrate. Phosphorylation of Ste2 is then thought to release Sst2, preventing it from being endocytosed with Ste2 and degraded as described above. Additional regulators exert feedback control on receptor-mediated signaling both upstream and downstream of the receptor (Figure 2). For example, the genes encoding Bar1, a pepsin-like aspartyl protease that cleaves α -factor, and Msg5, a dual-specificity MAPK-specific phosphatase that dephosphorylates and thereby inactivates Fus3, are also induced in response to pheromone.

Pheromone Receptor Biogenesis

The most is known about synthesis of Ste2 because it has been the most extensively studied. Mature Ste2 is inserted into the

Figure 3 Primary structure of *S. cerevisiae* Ste2 (α-factor receptor). The amino acid sequence of Ste2, in the one-letter code, is arranged to represent the seven membrane-spanning elements in their presumed topology across the plasma membrane. Note that some membrane-spanning segments are predicted to be longer than others, suggesting that the longer transmembrane domains are tilted relative to the plane of the membrane, as has been observed in the structures of other GPCRs (i.e., rhodopsin). Residues discussed in the text that have key functional properties in receptor signaling and adaptation are shaded according to their role in ligand recognition and receptor activation (blue), conformational constraint (green), G-protein activation (purple), phosphorylation (black), and ubiquitination (red). Two sites in the extracellular amino terminus are modified by N-linked glycosylation (CHO) are shaded gray. The consensus site for attachment of Asn-linked oligosaccharide (N-x-T or N-x-S) at residue 25 is used close to 100% of the time, whereas that at residue 32 is used only about 50% of the time, and that at residue 46 is not used at all, presumably because it is too close to the membrane for recognition by the eight-subunit oligosaccharyltransferase enzyme complex that transfers the mannose-rich core oligosaccharide from its membrane-bound dolichol carrier to N-X-T or N-X-S motifs in secreted and membrane-localized proteins. Certain naturally occurring neutral polymorphisms exist in the primary structure of Ste2, specifically residue 269 is E in some *S. cerevisiae* strains, but K in others.

plasma membrane such that it spans the membrane 7 times (Figure 3). Biogenesis of Ste2 commences with its import into the endoplasmic reticulum (ER) via a hydrophobic, uncleaved, N-terminal signal peptide, with concomitant addition of two Asn-linked oligosaccharides, which are further modified and extended with mannose-rich outer chains during transport of Ste2 through the Golgi complex. Although N-glycosylation does not seem to be critical for receptor function, it may direct or stabilize proper folding of Ste2. While still in the secretory pathway, Ste2 self-associates to form dimers or perhaps larger oligomers. Mutational studies and cross-linking analysis indicate that TMD1 is especially important for this self-association. Oligomerization appears to be important for efficient trafficking of Ste2 to the plasma membrane and may be important for the signaling competent state of Ste2, but oligomerization does not appear to be modulated by ligand binding. Receptors that fold improperly in the ER are ultimately degraded by ER quality-control mechanisms; those misfolded receptors that make it

to the Golgi compartment get sorted to the vacuole (equivalent of the mammalian lysosome) for degradation. It is not clear where or when properly folded and oligomerized receptors first encounter and couple to the quiescent form of the $G\alpha\beta\gamma$ heterotrimer (Gpa1–Ste4–Ste18). However, some studies indicate that receptors are present in significant excess over their cognate G-protein; if so, there is a significant reservoir of receptors at the plasma membrane that are not associated with the heterotrimeric G protein in preactivation complexes primed for the arrival of their pheromone ligand.

Pheromone Receptors Bind Ligand via Contacts with the Extracellular Ends of the Transmembrane Segments

The ligand-binding site in the pheromone receptors (and in other seven-transmembrane-segment G-protein-coupled

receptors (GPCRs)) are conceivably rather complex, in that they have the potential to be composed of determinants that reside within the seven-transmembrane segments, and/or the three extracellular loops and the extracellular N-terminal extension (or combinations of these elements). The lipid modification of α -factor has prevented the application of standard methods for analyzing its binding to Ste3. Hence, the binding of α -factor to Ste2 has been examined in much greater detail. A combination of genetic and biochemical studies strongly implicates residues near the extracellular ends of the transmembrane segments (TMDs) as forming the α -factor-binding pocket. These observations suggest a model for receptor activation in which ligand binding to the ends of the TMDs could influence the relative packing or overall structural arrangement of all or part of the seven-helix bundle. The resulting conformational change could then be relayed to the intracellular side, and thereby communicated to the associated G protein to promote its release of GDP and binding of GTP. Two residues in Ste2 that are necessary for pheromone-induced receptor activation are Phe204, situated near the end of TMD5, which is required for high-affinity α -factor binding, and Tyr266, located near the end of TMD6, which, although not important for binding affinity *per se*, is nonetheless needed for subsequent signaling. The extracellular ends of TMDs 5 and 6 are, of course, directly connected to their intracellular ends, and the third intracellular loop of Ste2, which spans the intracellular ends of TMDs 5 and 6, has been implicated in G-protein activation. This situation provides a ready explanation for how conformational change upon pheromone binding could be directly coupled to the associated G protein. Current studies suggest that residues near the extracellular ends of several other TMDs in Ste2 are also involved in ligand binding, indicating that the binding pocket for α -factor is composed of a microdomain formed by the ends of multiple TMDs. Likewise, the crystal structures of antagonist-bound forms of two mammalian GPCRs (β 2-adrenergic receptor and A2A adenosine receptor) show these drugs nest within the palisade created by the exocellular ends of several TMDs.

Pheromone Receptor Activation May Involve Relief of Conformational Constraint

Current models for signaling by GPCRs suggest that, in the absence of ligand, the receptor is maintained in the off-state in a restricted conformation and that ligand binding induces conformational changes that result in greater flexibility. Insights about the conformational state of Ste2 that accompanies its activation have been provided by analysis of constitutively active mutants that signal in a ligand-independent manner. These mutations primarily alter residues within the TMDs in a manner expected to perturb α -helix packing in the membrane, suggesting that constitutive activity can result from changes in the packing of the bundle of transmembrane α -helices. One very interesting example is the high degree of constitutive receptor activity caused by substitutions that alter the conserved Pro258 residue in TMD6 of Ste2. Pro residues have the unique property of introducing a kink in a TMD because -X-Pro- bonds lack an amide hydrogen and, therefore, cannot form the main chain H-bond interaction that stabilizes

the rest of the backbone of an α -helix. Thus, substitution of Pro258 with other residues should affect the structure of TMD6. Moreover, TMD6 is the segment whose intracellular end is the most proximal to those residues in the third intracellular loop most strongly implicated in G-protein activation. Hence, the effect of substitution of Pro258 in TMD6 may reflect the conformational change induced within TMD6 that normally occurs only upon ligand binding. Interestingly, in *C. neoformans*, a pheromone receptor-like protein Cpr2 is necessary for proper morphogenesis during mating, but seems to function in a ligand-independent manner; interestingly, this protein contains Leu (instead of Pro) at the equivalent position in TMD6, perhaps explaining its constitutive-signaling activity. In this regard, it is also noteworthy that the majority of mammalian receptors of this class also contain Pro at a similar position in TMD6. Although mutation of Pro in TMD6 does not always lead to constitutive activity, it has frequently been implicated in receptor activation, suggesting mechanistic similarities in the activation process from yeast to humans. Comparison of the predicted structure of Ste2 with the well-studied photoreceptor rhodopsin has further identified other microdomains in common between the fungal pheromone receptor Ste2 and mammalian GPCRs. These comparisons also support the idea that a general underlying mechanism for activation of a wide range of receptors involves the movement of TMDs 1, 2, 3, and 4 away from the TMDs 5, 6, and 7.

Pheromone Receptors Promote G-Protein Activation via the Third Intracellular Loop

The residues on the cytoplasmic surface of pheromone receptors that contact the G protein and promote GDP-GTP exchange on the $G\alpha$ -subunit have not been pinpointed precisely. Analysis of chimeras between Ste2 and Gpa1 indicates that merely bringing the receptor and G protein into close proximity is not sufficient to stimulate GDP-GTP exchange because ligand stimulation is still required for activation of downstream signaling by such receptor- $G\alpha$ hybrids. As discussed above, current evidence suggests that pheromone binding promotes a conformational change at the extracellular ends of the transmembrane helical bundle in Ste2 that is propagated to the intracellular ends of the transmembrane segments, thereby probably exposing previously buried residues that promote G-protein activation. The identification of the critical residues has been challenging to identify by mutagenesis studies, suggesting that the interaction may involve multiple contacts between the receptor and G protein. However, several mutagenesis studies indicate that, in Ste2, the third intracellular loop certainly plays a key role. Consistent with this view, biochemical studies have demonstrated conformational changes in the third intracellular loop that are induced upon ligand binding. Remarkably, functional ligand-dependent Ste2 can be reconstituted by coexpressing halves of the receptor that are split in the middle of the third intracellular loop. Thus, it is possible that the residues closest to where TMDs 5 and 6 exit the plasma membrane are the most important for G-protein activation, assuming that the residues closest to the cut ends of such split receptors are the least likely to remain in their native condition. However, substitution of Leu236 (with His) very

near to the 'middle' (at least in terms of primary sequence) of the third loop, yields a Ste2 mutant that is strongly defective in promoting signaling yet displays an essentially wild-type level of surface expression, an essentially wild-type ability to bind α -factor, and an essentially wild-type level of association with the $G\alpha\beta\gamma$ heterotrimer, suggesting it is specifically defective in activation of the associated G protein. Interestingly, Ste2 (L236H) still undergoes ligand-stimulated endocytosis, indicating that the conformational changes and the determinants recognized by the endocytic machinery are distinct from those required for G-protein activation.

One major difficulty in understanding of the mechanism of G-protein activation is the fact that, although Ste2 and Ste3 both act through the same G protein (Gpa1–Ste4–Ste18), Ste2 and Ste3 do not share any recognizably significant tracts of sequence similarity, even at the intracellular ends of TMDs 5 and 6 or within the third intracellular loop. In this same regard, certain GPCRs from other organisms, including mammals, have been expressed in *S. cerevisiae* and, in response to the appropriate agonist, are able to activate, albeit to different extents, the endogenous yeast G protein. Again, this cross-species functionality occurs even though the heterologous receptors do not share any obvious sequence identity with the yeast pheromone receptors. Similarly, Ste2 expressed in mammalian cells is able to activate signaling in response to α -factor. Although the ability of diverse receptors from yeast to man to activate the same set of G proteins suggests a common mechanism underlying receptor and G-protein activation, the structural determinants of that common action are not readily apparent. Nevertheless,

continued functional studies of the yeast pheromone receptors are likely to continue to shed light on how this important class of receptors operates.

Glossary

Autophagy Literally, 'self-eating'; a process of intracellular degradation of biomolecules and cellular components by which the constituents (e.g., amino acids) can be recycled by the cell.

Endocytosis The process by which regions of plasma membrane and any embedded proteins are brought inside the cell by formation of a membrane-bound intracellular vesicle.

Endosome The membrane-bound intracellular vesicle formed by the process of endocytosis.

Phagocytosis Uptake of particles such as cell fragments or bacteria by engulfing and then internalizing them in a membrane vesicle.

Phagosome The membrane-bound intracellular vesicle formed by the process of phagocytosis.

Phosphatidylinositol (PtdIns) A membrane lipid consisting of a pair of membrane embedded fatty acid chains linked to a surface-exposed inositol head group. The hydroxyl groups of the inositol may be phosphorylated by PI kinases at the 3', 4', and 5' positions.

Phosphatidylinositol is a polar phospholipid which comprises a small fraction of the total membrane lipids in cells. The hydroxyl moieties of the inositol head group may be reversibly modified by transfer of a phosphate group from adenosine triphosphate (ATP) to one or more of three positions. This reaction is catalyzed by the class of enzymes referred to as phosphatidylinositol kinases (PI kinases). Specific PI kinases can produce three monophosphorylated phosphatidylinositols, PtdIns(3)P, PtdIns(4)P, and PtdIns(5)P, in intact cells. These can be further phosphorylated by PI kinases to yield polyphosphoinositides such as PtdIns(4,5)P₂ and PtdIns(3,4,5)P₃, which function in regulating plasma membrane activities and cell signaling cascades, respectively. Although it is likely that PtdIns(4)P and PtdIns(5)P have important functions, molecular targets of these phosphoinositides have yet to be characterized. In contrast, through both genetic and biochemical studies our understanding of PtdIns(3)P functions and the PI 3-kinases which specifically produce PtdIns(3)P are well advanced. In recent years, a large number of proteins that interact with PtdIns(3)P have been discovered and their roles in various cellular processes, including membrane trafficking, autophagy, and signaling, have been elucidated.

Synthesis and Turnover of PtdIns(3)P

Although PtdIns(3)P synthesis was not thought to be acutely activated by extracellular stimuli as is the case for certain other phosphoinositides, PtdIns(3)P content of membranes appears to be dynamically regulated and spatially restricted in intracellular compartments. Current data indicate that PtdIns(3)P is found primarily, and perhaps exclusively, in endosomal membranes (Figure 1). These membranes are vesicular structures which delimit compartments derived from endocytic internalization of patches of membrane from the cell surface. Mechanisms for generation of PtdIns(3)P must therefore be activated concurrently with or shortly after endocytosis, while turnover of PtdIns(3)P by hydrolysis or additional phosphorylation must occur during the progression of endosomes toward

their cellular fates. These fates include recycling to the plasma membrane and fusion with lysosomes. Cellular proteins embedded in these membrane patches can likewise be targeted for recycling back to the plasma membrane where they may resume their functions, or for degradation in the lysosome. Many studies have shown that PtdIns(3)P and its molecular targets play critical regulatory roles in such membrane trafficking pathways of endosomes, and thus help to determine the cellular distribution and fate of membrane proteins such as receptors for growth factors.

Synthesis of PtdIns(3)P by PI 3-Kinases and Phosphoinositide Phosphatases

In the yeast genome, a single gene encoding a PtdIns 3-kinase has been identified. *VPS34* was originally identified in a screen for mutants that failed to properly direct a protein degradation enzyme to the vacuole, the organelle with functions similar to the lysosome of animal cells. The 100-kDa protein encoded by this gene, *Vps34p*, has a domain highly similar to mammalian PI 3-kinase and was subsequently shown to have PI 3-kinase activity. *Vps34p* exists in a complex with a 150-kDa serine/threonine kinase, *Vps15p*, which serves to target the *Vps34p* enzyme to membranes where its substrate phosphatidylinositol resides. Phosphorylation of *Vps34p* by the protein kinase activity of *Vps15p* is required for full activity of the *Vps34p* PI 3-kinase. A homologous PI 3-kinase complex exists in all eukaryotes studied. The mammalian *Vps34* PI 3-kinase (also referred to as a class III PI 3-kinase) appears to be the predominant enzyme which produces PtdIns(3)P in cells. Although class I and II PI 3-kinases are also capable of phosphorylating PI *in vitro*, their contribution to PtdIns(3)P production *in vivo* has not been well established.

PtdIns(3)P may also be produced by the action of phosphoinositide 4-phosphatases such as INPP4A and INPP4B on PtdIns(3,4)P₂, or of phosphoinositide 5-phosphatases including Sac3 on PtdIns(3,5)P₂. The Sac3 ortholog in yeast, Fig4p, appears to be regulated in concert with the yeast PtdIns(3)P

Figure 1 Production and turnover of PtdIns(3)P in endosomal membranes. In the process known as endocytosis patches of plasma membrane invaginate as a result of formation of clathrin coats. Subsequent scission from the plasma membrane and uncoating of these vesicles produce early endosomes where PtdIns(3)P is produced by the Vps34 PI-3 kinase. PtdIns(3)P also persists on the limiting membrane as well as intraluminal vesicles of the multivesicular endosome, a product of fusion of early endosomes. During subsequent maturation, the PtdIns(3)P may be hydrolyzed by the action of myotubularin family PI-phosphatases, or further phosphorylated by the PIKfyve/Fab1p PI 5-kinases to produce PtdIns(3,5)P₂. These reactions may also take place in the intraluminal vesicles.

5-kinase Fab1p (see below), suggesting that the synthesis of PtdIns(3)P and PtdIns(3,5)P₂ are in a tightly coupled cycle in the yeast endomembrane system.

Dephosphorylation of PtdIns(3)P

PtdIns(3)P may be converted back to phosphatidylinositol by the action of a 3-phosphatase, an enzyme which catalyzes the hydrolysis of the phosphate group on the 3' position of the inositol ring. A number of phosphoinositide phosphatases have been characterized in yeast and mammalian systems, but, to date, activity against PtdIns(3)P has been attributed only to members of the myotubularin family. This family consists of at least 16 genes in humans with one putative homolog in yeast. Of the human proteins, nine have functional phosphatase domains; the others have similar protein sequences but apparently no catalytic activity. These proteins also have potential phosphoinositide-binding PH domains while two have FYVE domains likely to specifically target PtdIns(3)P. Details regarding the activity of myotubularin proteins in cells have yet to be reported. However, mutations in a number of human myotubularin genes have been linked to neuromuscular diseases pointing to significant roles in the development or function of neural and muscle tissues.

Phosphorylation of PtdIns(3)P

In addition to hydrolysis of the 3-phosphate group by phosphatases, PtdIns(3)P levels may be modulated by additional

phosphorylation. It is known that significant levels of PtdIns(3,5)P₂ are present in yeast and mammalian cells. This phosphoinositide appears to be formed primarily by phosphorylation of PtdIns(3)P at the 5' position of the inositol ring. The Fab1 protein of yeast and a mammalian homolog called PIKfyve possess this enzymatic activity. Both of these proteins are also able to bind specifically to PtdIns(3)P via an FYVE domain. Conversion of PtdIns(3)P to PtdIns(3,5)P₂ not only would serve to terminate PtdIns(3)P-dependent cellular functions, but may also contribute to cellular responses to osmotic stress or other signals as well as to maturation of endosomes.

Molecular Targets and Cellular Functions of PtdIns(3)P

Protein Domains that Bind to PtdIns(3)P

Two structurally unrelated protein domains have been shown to bind to PtdIns(3)P. The first to be discovered was the FYVE domain (named for the first four proteins in which it was recognized, Fab1p, YOTB, Vac1p, and EEA1). The domain is characterized by a RING finger structure which binds two Zn molecules. It is found in five yeast proteins and 35 human proteins. Binding of FYVE domains to PtdIns(3)P-containing membranes relies on a combination of nonspecific membrane interactions and a groove which specifically accommodates the phosphate group of PtdIns(3)P while sterically excluding other phosphoinositide head groups. To date, all FYVE domains studied bind exclusively to PtdIns(3)P.

The phox homology (PX) domain was first recognized in two components of the phagocyte nicotinamide adenine

dinucleotide phosphate (NADPH) oxidase (phox) complex (p40phox and p47phox). It is structurally unrelated to the FYVE domain except for a somewhat similar binding pocket which accommodates the inositol 3-phosphate head group. However, comparison of the crystal structures of the p40phox PX domain bound to dibutanoyl PtdIns(3)P and the FYVE domain of early endosome antigen-1 (EEA1) bound to the head group inositol 1,3-bisphosphate indicates that both proteins utilize basic residues to bind both phosphate and hydroxyl groups in the lipid head group. All 15 PX domains in yeast bind PtdIns(3)P with varying affinities. Of the mammalian proteins characterized, many bind PtdIns(3)P strongly, while several have lower affinity for other, and in some cases several, phosphoinositides.

Recently, the GRAM-like, ubiquitin-binding on Eap45 (GLUE) of the Vps36 subunit of the ESCRT sorting complex (ESCRT, endosomal sorting complex required for transport) has been shown to be required for recognition of PI(3)P-containing membranes. This domain shows little similarity to either the PH or FYVE domain.

PtdIns(3)P-Binding Proteins in Endosomal Membrane Trafficking

In accordance with the predominant localization of PtdIns(3)P to membranes of the endosomal system, several PtdIns(3)P-binding proteins have been shown to function in various steps of endosome fusion, sorting, and maturation (Table 1). In mammalian cells, a major function of these events is to direct membrane components to the lysosome, whereas sorting of proteins to the vacuole is a major function in yeast.

Following internalization of plasma membrane patches to form small membrane vesicles denoted as early endosomes, a process of maturation is initiated which involves fusion of early endosomes into larger multivesicular bodies. These multivesicular bodies form specialized subdomains marked by the recruitment of different sets of proteins. Eventually these specialized domains and their cargo proteins form new compartments, which may then be returned to the plasma membrane or delivered to lysosomes or the trans-Golgi complex.

Table 1 Cellular functions of PtdIns(3)P and some associated proteins

Cellular function	Domain	PtdIns(3)P-binding proteins
Endosome fusion/maturation	FYVE	EEA1, rabenosyn-5, PIKfyve/Fab1p
Golgi-vacuole trafficking (yeast)	FYVE PX	Vps27p, Vac1p, Fab1p Grd19p, Mvp1p, Vps5p, Vam7p
Receptor sorting/targeting to lysosome	FYVE PX GLUE	Hrs Sorting nexins Vps36p
Signal transduction	FYVE PX	SARA CISK
Phagosome function/maturation	FYVE PX	EEA1 p40 ^{phox}

This process is controlled in part by various members of the small guanine triphosphatase (GTPase) Rab family. Rab5 in particular is required for fusion of early endosomes and it accomplishes this in part by stimulating the production of PtdIns(3)P via Vps34, with the resulting recruitment of PtdIns(3)P-binding proteins to the endosomes. Such proteins include EEA1 and rabenosyn-5, which both bind Rab5 itself as well as PtdIns(3)P via a FYVE domain. Once recruited to the endosome through these mechanisms, EEA1 and rabenosyn-5 appear to function in the tethering, docking, and ultimate fusion of early endosomes.

The ESCRT machinery conserved in yeast and consists of several multiprotein complexes and is critical in the trafficking of ubiquitinated cargo proteins and maturation of endosomes. The FYVE-domain protein Hrs binds PtdIns(3)P and is a subunit of the ESCRT-0 complex. Likewise, binding of PtdIns(3)P (and likely other phosphoinositides) via the GRAM-like ubiquitin binding in EAP45 (GLUE) domain is required for the function of the ESCRT-II subunit Vps36.

The sorting nexin (SNX) family containing up to 25 human proteins and the yeast homologs Mvp1p, Vps5p, Vps17p, and Grd19p all contain a PX domain. All of the yeast SNX proteins and some of the mammalian counterparts have been found to bind preferentially or specifically to PtdIns(3)P, and most characterized SNX proteins localize at least partially to endosomes. Consistent with the importance of PtdIns(3)P in vacuolar protein sorting in yeast, Vps5p and Vps17p have a role in the retrieval of the vacuolar protein sorting receptor Vps10p, while Mvp1p and Grd19 participate in Golgi to vacuole trafficking. In mammalian cells, roles of the various SNX proteins are being assigned, and the emerging picture suggests that different sorting nexins may be required for regulating the distinct fates of endosomes, that is, recycling to the cell surface, delivery to lysosomes, or delivery to the trans-Golgi.

PtdIns(3)P in Phagocytosis and Bacterial Invasion

Many of the PtdIns(3)P-binding proteins involved in the endocytic process are likely involved in the similar processes of phagocytosis and host cell invasion by bacteria and parasites. Phagosomes, like endosomes, form by invagination of patches of the plasma membrane followed by 'pinching off' and sealing to form a self-contained intracellular compartment. PtdIns(3)P appears transiently on phagosomes in a manner which parallels its appearance and disappearance in endosomes. Phagosomal PtdIns(3)P is apparently generated by the targeting and activation of the VPS34 PI 3-kinase. As in early endosomes, the PtdIns(3)P synthesized in phagosomes recruits FYVE- and PX-domain containing proteins including EEA1. Likewise, in the process of secretion-mediated invasion by *Salmonella*, the membrane vacuole which envelops the invading bacterial cells accumulates PtdIns(3)P. In certain cell types, recruitment of the NADPH oxidase to phagosomes may occur via PX domains in its p40 and p47 subunits. This mechanism may contribute to defense against pathogens since the NADPH oxidase produces reactive oxygen species toxic to invading bacterial cells. Disruption of this recruitment mechanism by pathogenic bacteria enhances their ability to escape host cell defenses.

PtdIns(3)P and Signaling from the Endosomal System

Recently, it has become clear that the endosomal system is an essential component of signal transduction pathways regulating proliferation, survival, differentiation, and stress responses. Current evidence suggests that growth factor receptors, many of which are internalized into endosomes following binding of their ligands, can continue to generate signals to downstream effectors as they transit through the endosomal system. Furthermore, internalization and delivery of such receptors to lysosomes for degradation is an important mechanism for downregulation of signaling in a variety of systems.

The FYVE-domain protein, SARA, localizes to early endosomes via its association with PtdIns(3)P. SARA also binds to Smad2, a downstream target of the transforming growth factor- β (TGF β) receptor. Association of the SARA–Smad complex appears to be essential for efficient phosphorylation of Smad by the internalized receptor. The related FYVE-domain protein endofin may play a similar role in Smad1 binding and bone morphogenetic protein (BMP) signaling. Thus, PtdIns(3)P in endosomes can serve to assemble signaling complexes in which the local concentration of components is increased by association with specific intracellular membranes. The FYVE domain-containing protein homolog of the yeast protein Vps27p (Hrs) may function in a similar manner in the TGF β signaling pathway. However, in its function in the ESCRT complex, Hrs may promote the internalization and ultimate degradation of growth factor receptors. Thus, there is precedent for the involvement of PtdIns(3)P-binding proteins in attenuation as well as enhancement of growth factor signals.

Endosomal localization via PtdIns(3)P binding may also serve to target or sequester components of signaling pathways several steps removed from the initial receptor signal. The PX domain-containing protein kinase CISK (also denoted SGK3) is localized to endosomes and may function in this way. Like its related family members Akt and SGK, CISK is activated by regulatory protein kinases in response to growth factor-mediated regulation of PtdIns 3-kinases that produce PtdIns (3,4,5)P₃. Based on its endosomal disposition, it seems likely that the substrates of the CISK protein kinase are similarly localized. Few specific substrates have been identified but an effect on hair follicle growth and development in knockout mice suggests an important role for CISK in epithelial and follicle development.

PtdIns(3)P may also serve as a component of the cellular stress response. In yeast and mammalian cells, PtdIns(3,5)P₂ is formed in response to osmotic stress by the FYVE-domain

proteins Fab1p and PIKFYVE, respectively. Effectors of PtdIns (3,5)P specific for this function have not been identified.

Vps34 and Mammalian Target of Rapamycin Signaling and Control of Autophagy

The mammalian target of rapamycin (mTOR) protein kinase is a key component in control of cell growth in response to nutrients, and affects processes such as protein synthesis that are highly dependent on cellular stores of energy and raw materials. Recent studies have implicated the class III PtdIns 3-kinase Vps34 as a positive regulator of the mTOR response to amino acids. Conversely, mTOR is a negative regulator of autophagy, frequently a response of cells to starvation conditions. Surprisingly, Vps34 has also been shown to play an essential role in autophagy, while the myotubularin family PtdIns 3-phosphatase jumpy appears to act as a negative regulator of this process. These results suggest that control of PtdIns(3)P levels, perhaps at specific cellular locations such as membrane systems involved in autophagy, may be key control points for autophagy as well as cellular responses to nutrient levels.

Glossary

PH domain A protein domain composed of approximately of 100 amino acids which can specifically bind to PtdIns-4,5-P₂ and PtdIns-3,4,5-P₃.

Phosphatidylinositol A membrane phospholipid, which is a precursor to all known phosphoinositides and is composed of an inositol head ring and a fatty-acid tail.

Phosphoinositide A phospholipid second messenger, which is found in intracellular membranes and which can be phosphorylated on the inositol head ring at the D-3, D-4, and D-5 positions resulting in seven known phosphorylated species.

Phosphoinositide kinase An enzyme which can use phosphoinositides as substrates, and can phosphorylate the inositol head ring at either the D-3, D-4, or the D-5 positions.

Phosphoinositide phosphatase An enzyme which can specifically remove the D-3, D-4, or D-5 phosphate from phosphorylated phosphoinositides.

Phospholipase An enzyme which can hydrolyze the phosphodiester bond in phospholipids and produce soluble inositol lipids and membrane-bound diacylglycerol; type C phospholipases specifically use phosphoinositides as substrates.

Phosphatidylinositol (PtdIns) is a minor membrane phospholipid, which is found in all eukaryotic cells. It is the precursor of a family of phosphorylated lipids, which are collectively known as phosphoinositides, and rather than serving a structural role in cellular membranes, they act as functional second messengers to transduce biochemical signals in the cell. This article discusses in detail the synthesis, hydrolysis, and cellular functions of phosphatidylinositol bisphosphate and trisphosphate.

Phosphoinositides are composed of a water-soluble inositol ring, which can be phosphorylated at each of three positions (D-3, D-4, and D-5), and a greasy fatty-acid tail which is attached to a glycerol and linked to the inositol ring by a phosphodiester bond (Figure 1). The concerted actions of phosphoinositide kinases, phosphoinositide phosphatases, and phospholipases on phosphatidylinositol lead to the production of seven additional phosphoinositides which are known to exist in cells (Figure 2). Of these, phosphatidylinositol-4,5-bisphosphate (PtdIns-4,5-P₂) and phosphatidylinositol-3,4,5-trisphosphate (PtdIns-3,4,5-P₃) are the best understood and characterized. Both the synthesis and the degradation of PtdIns-4,5-P₂ and PtdIns-3,4,5-P₃ are tightly regulated, and this ensures efficient and coordinated signaling through these second messengers. Biochemical and genetic studies have implicated both PtdIns-4,5-P₂ and PtdIns-3,4,5-P₃ in numerous cellular responses, such as cell growth, cell survival, cell motility and modulation of the actin cytoskeleton, gene transcription, and vesicle trafficking (Figure 3). The importance of these phosphoinositides in cell biology is exemplified by the fact that deregulation in the metabolism or mechanism of action of these lipids often results in human diseases such as cancer and type 2 diabetes.

Phosphatidylinositol-4,5-Bisphosphate

Synthesis

Phosphatidylinositol-4,5-bisphosphate (PtdIns-4,5-P₂) is often considered to be one of the most important functional lipids

in eukaryotic cells, because it not only has a functional second messenger role *per se*, but can also serve as an intermediate for the production of additional lipid mediators. It can serve as a substrate for phosphoinositide 3-kinase (PI 3-K) to produce phosphatidylinositol-3,4,5-trisphosphate (PtdIns-3,4,5-P₃), it can be hydrolyzed by phospholipases to produce diacylglycerol (DAG) and soluble inositol phosphates, and it can also be dephosphorylated by D-4 and D-5 lipid phosphatases (Figure 2). Although the bulk of PtdIns-4,5-P₂ is found at the plasma membrane, other distinct pools of PtdIns-4,5-P₂ have been reported. For example, there exists a nuclear phosphoinositide cycle where PtdIns-4,5-P₂ production has been detected. However, there are relatively modest, if any, changes in the total levels of PtdIns-4,5-P₂ upon cellular stimulation with agonists such as growth factors or hormones. This is difficult to reconcile with the second messenger hypothesis, which dictates that a lipid mediator must rapidly accumulate to amplify downstream signaling. Therefore, it is likely that the constitutive levels of PtdIns-4,5-P₂ change locally at discrete intracellular sites, such that the accumulation of this lipid is regulated both spatially and temporally. In addition, there are two other isomers of phosphatidylinositol bisphosphate: PtdIns-3,4-P₂ and the recently discovered PtdIns-3,5-P₂. The function of these two phosphoinositides is not entirely clear, but they are likely to mediate certain responses downstream of PI 3-K.

The synthesis of PtdIns-4,5-P₂ is controlled by the sequential action of phosphoinositide 4-kinases, which use phosphatidylinositol (PtdIns) as substrate and produce PtdIns-4-P, and phosphoinositide phosphate kinases (PIPKs), which can use either PtdIns-4-P or PtdIns-5-P as substrates. In both cases, the product is PtdIns-4,5-P₂ (Figure 2). Much is known about the enzymes which produce PtdIns-4,5-P₂. There are two families of PIPKs, type I and type II. Type I kinases preferentially phosphorylate PtdIns-4-P at the D-5 position, and this appears to be the major route of PtdIns-4,5-P₂ synthesis. However, it was recently discovered that type II PIPKs can phosphorylate

Figure 1 Structure of phosphatidylinositol-4,5-bisphosphate. The structure shows PtdIns-4,5- P_2 , which contains an inositol head group connected to a diacylglycerol via a phosphodiester linkage. The fatty acid moiety is typically stearyl-arachidonyl. The inositol head group can be phosphorylated at one of three positions, D-3, D-4, and D-5. Shown are phosphate groups at the D-4 and D-5 position in PtdIns-4,5- P_2 . Phosphoinositide 3-kinases phosphorylate the D-3 position of PtdIns-4,5- P_2 to produce PtdIns-3,4,5- P_3 .

Figure 2 Phosphoinositide metabolism. The pathways responsible for the production of all known phosphoinositides are shown. The concerted actions of phosphoinositide kinases, such as type I and type II phosphoinositide 4-phosphate and 5-phosphate kinases (PIPKs) and phosphoinositide 3-kinases (PI 3-K), as well as phosphatases (PTEN and SHIP), leads to the production of seven distinct phosphoinositides, from the precursor phosphatidylinositol (PtdIns). Although all of the forward (solid arrows, mediated by kinases) and reverse (broken arrows, mediated by phosphatases) reactions are possible, the pathways which are likely to predominate in cells are shown in bold arrows.

PtdIns-5-P at the D-4 position, and so it is likely that in some instances, this represents an important pathway for the generation of PtdIns-4,5- P_2 . Several forms of both type I and type II PIPKs exist in mammalian cells, and homologs are also found in lower eukaryotes, such as yeasts, highlighting the importance of these enzymes in biology. The crystal structure of a type II enzyme has been solved, and has revealed an elongated, flat surface covered with highly basic, positively charged amino acids, which are ideally positioned for interaction with the negatively charged phosphoinositides such as PtdIns-5-P. Finally, a separate route of synthesis for PtdIns-4,5- P_2 is the dephosphorylation of PtdIns-3,4,5- P_3 by D-3 phosphoinositide phosphatases, though it is not clear what fraction of the bulk PtdIns-4,5- P_2 pool is accounted for by this mechanism. Regardless, PIPKs represent the major pathway leading to the production of PtdIns-4,5- P_2 , and as such their activities are tightly controlled.

Hydrolysis

PtdIns-4,5- P_2 is hydrolyzed by phosphoinositide-specific phospholipases. These enzymes, also known as type C phospholipases (PLC), hydrolyze PtdIns-4,5- P_2 into two important second messengers: the membrane-bound fatty acid moiety, also known as DAG, and the soluble portion, which is an inositol trisphosphate (Ins-1,4,5- P_3 , when PtdIns-4,5- P_2 is the PLC substrate). Each of these products has important roles in lipid signaling. DAG is the activator for members of the protein kinase C family of serine/threonine kinases, which are recruited to the membrane at the site of DAG production. Ins-1,4,5- P_3 plays an equally important role in lipid signaling as it is responsible for the release of Ca^{2+} from internal stores, such as the endoplasmic reticulum.

Although four distinct families of PLC exist in mammalian cells, they all share a similar catalytic mechanism employing

Figure 3 Targets of PtdIns-4,5- P_2 and PtdIns-3,4,5- P_3 . A large number of proteins whose activities are directly regulated by either PtdIns-4,5- P_2 or PtdIns-3,4,5- P_3 exist. A few of these are depicted and serve to illustrate that the binding of the phosphoinositide to the protein can alter its cellular location as well as directly influencing catalytic activity when enzymes are the targets. These interactions are responsible for the activation of secondary signaling pathways, which ultimately lead to numerous physiological responses, as depicted. In many cases, PtdIns-4,5- P_2 and PtdIns-3,4,5- P_3 have overlapping functions, due to the activation of distinct effector molecules, such as the remodeling of the actin cytoskeleton, which occurs as a consequence of both PtdIns-4,5- P_2 - and PtdIns-3,4,5- P_3 -dependent signaling.

calcium as a cofactor. All members of the PLC family use PtdIns-4-P and PtdIns-4,5- P_2 as substrates. PLC β enzymes are regulated by binding to both $\beta\gamma$ - as well as α -subunits of heterotrimeric GTP-binding proteins. PLC δ also appears to be regulated by G proteins, although the mechanism is unclear, and it is also reported that increases in Ca^{2+} alone are sufficient to activate PLC δ . Phospholipases belonging to the PLC γ family are activated by the binding of SH2 domains to phosphotyrosine-containing sequences in receptor tyrosine kinases, and as such participate in growth-factor-dependent responses such as cell growth. Tyrosine phosphorylation of PLC γ is also important in controlling catalytic activity. Very recently, a new PLC subtype has been described, PLC ϵ , and has been shown to be a novel effector of the GTP-bound form of the Ras GTPase. The diversity and complexity of the PLC family underscore the importance of PtdIns-4,5- P_2 hydrolysis and DAG/Ins-1,4,5- P_3 production in mediating cell proliferation, differentiation, and cell motility.

Cellular Function

In addition to serving as the substrate for additional lipid second messengers, PtdIns-4,5- P_2 is an important lipid mediator in its own right. Numerous studies have shown that PtdIns-4,5- P_2 can modulate the activity of proteins which regulate actin assembly, leading to rearrangements of the actin cytoskeleton (Figure 3). For example, PtdIns-4,5- P_2 has been shown to promote actin polymerization by directly interacting with actin-binding proteins such as profilin. Similarly, actin-capping proteins, such as CapZ, prevent spontaneous actin assembly by capping the free ends of actin filaments,

and the binding to PtdIns-4,5- P_2 disrupts this capping event leading to filament assembly. The list of actin-binding proteins whose activities are also regulated by PtdIns-4,5- P_2 includes gelsolin, cofilin, filamin, and vinculin. The small GTPase Rac also plays an important role in the remodeling of the actin cytoskeleton, and in some instances this requires PtdIns-4,5- P_2 . For example, the Ezrin, Radixin, and Moesin (ERM) family of proteins, a family of Rac effector molecules, are also PtdIns-4,5- P_2 -binding proteins which regulate dynamic actin assembly, again linking PtdIns-4,5- P_2 function to the actin cytoskeleton. Rac, in the active GTP bound form, also interacts with PIP kinases, which are responsible for PtdIns-4,5- P_2 synthesis. Recent studies in cells have provided further evidence that PtdIns-4,5- P_2 is a critical regulator of the actin cytoskeleton. For example, expression of type I PIPK enzymes in cells leads to a dramatic reorganization of the actin cytoskeleton, and PIPK I appears to be targeted to focal adhesions, sites of cellular contact with the extracellular matrix. This targeting provides clear evidence for the localized accumulation of PtdIns-4,5- P_2 in the cell. Studies such as these, carried out in mammalian cells, have also been corroborated in yeasts, whereby genetic ablation of PIP kinases (such as Mss4p) leads to abnormalities in the actin cytoskeleton, which can be rescued by the introduction of human PIPK isoforms.

PtdIns-4,5- P_2 is also an important cofactor for the activity of a number of signaling enzymes. The best example is for phospholipase D (PLD), an enzyme responsible for the production of phosphatidic acid (PA) in the cell. PLD requires PtdIns-4,5- P_2 for efficient catalytic function. As certain PIP kinases also depend on PA for enzymatic activity, and PtdIns-4,5- P_2 stimulates PLD leading to PA production, the net result is a positive amplification loop which leads to amplification of PA and PtdIns-4,5- P_2 synthesis at specific intracellular compartments where these enzymes are located. Both PIPKs and PLD have been implicated in trafficking and secretion, and as such, their products are directly involved in controlling vesicle formation, as well as endocytosis (Figure 3).

Phosphatidylinositol-3,4,5-Trisphosphate

Synthesis

Unlike its substrate PtdIns-4,5- P_2 , phosphatidylinositol-3,4,5-trisphosphate (PtdIns-3,4,5- P_3) is nominally absent in unstimulated cells and rapidly accumulates in response to virtually all known growth factors, hormones, cytokines, and other stimuli. In most cells, production of PtdIns-3,4,5- P_3 typically peaks within seconds to a few minutes after stimulation, and declines to near basal levels after 1–2 h. A second peak of PtdIns-3,4,5- P_3 has been observed in cells between 4 and 8 h after stimulation with mitogens such as platelet-derived growth factor (PDGF). This second peak of PtdIns-3,4,5- P_3 is responsible for efficient cell-cycle progression in fibroblasts, specifically entry into the S phase where DNA synthesis occurs. Although the bulk of PtdIns-3,4,5- P_3 is produced at the plasma membrane, it is also known that there are discrete intracellular locations where this phosphoinositide is also found, particularly the nucleus. PI 3-Ks are responsible for the production of PtdIns-3,4,5- P_3 in higher eukaryotes. These enzymes phosphorylate the D-3 position of the inositol head ring, and

depending on the substrate, four distinct products can result: PtdIns-3-P, PtdIns-3,5-P₂, PtdIns-3,4-P₂, and PtdIns-3,4,5-P₃ (Figure 1). Although different forms of PI 3-Ks exist, each with unique substrate selectivity, the class Ia enzymes are responsible for the production of PtdIns-3,4,5-P₃ in cells. These PI 3-Ks are composed of a p85 regulatory subunit and a p110 catalytic subunit. The regulatory subunit binds to specific phosphotyrosine-containing sequences in the cytosolic domains of activated receptor tyrosine kinases, via a tandem repeat of two Src-Homology 2 (SH2) domains. This interaction facilitates the activation of the catalytic subunit, whose activity is also increased by a direct interaction with the activated form of the small GTPase Ras. The newly activated PI 3-K converts PtdIns-4,5-P₂ to PtdIns-3,4,5-P₃. In addition, class Ib PI 3-Ks are also capable of producing PtdIns-3,4,5-P₃, and these kinases are typically activated downstream of heterotrimeric G protein-coupled receptors, such as the thrombin receptor in platelets. Class Ib enzymes are also composed of two subunits, a p120 catalytic subunit and a p101 regulatory subunit, which confers sensitivity to Gβγ. Class Ib enzymes also require activated Ras for full catalytic function. Thus, the primary route of synthesis for PtdIns-3,4,5-P₃ in cells is through the activation of class I PI 3-Ks, which use PtdIns-4,5-P₂ as substrate.

PtdIns-3,4,5-P₃ Phosphatases

As the production of PtdIns-3,4,5-P₃ is critical for a number of physiological responses in cells, mechanisms exist which mediate the termination of PI 3-K and PtdIns-3,4,5-P₃ signaling. PI 3-K lipid products, including PtdIns-3,4,5-P₃, are not degraded by phospholipases, but instead are downregulated by at least two different types of phosphoinositide phosphatases. SHIP1 and SHIP2 (SH2-containing inositol 5'-phosphatases) are lipid phosphatases which specifically remove the D-5 phosphate from both PtdIns-3,4,5-P₂ and PtdIns-3,4,5-P₃ (Figure 2). The action of SHIP1/2 on PtdIns-3,4,5-P₃ results in the production of PtdIns-3,4-P₂, and although this can impair signaling downstream of PI 3-K, PtdIns-3,4-P₂ is able to mediate certain responses which overlap with PtdIns-3,4,5-P₃. Despite this, loss of SHIP2 increases insulin sensitivity in responsive tissues such as muscle and fat. Phosphatase and tensin (PTEN) homolog deleted on chromosome 1 is a D-3 phosphatase which dephosphorylates PtdIns-3,4,5-P₃ with PtdIns-4,5-P₂ as the product (Figure 2). PTEN is very effective at terminating PI 3-K and PtdIns-3,4,5-P₃ signaling, and this is evidenced by the fact that mutations in the PTEN gene have been detected in a large fraction of advanced human tumors. For this reason, PTEN is referred to as a tumor-suppressor gene. Thus, efficient termination of PtdIns-3,4,5-P₃ signaling is of critical importance for intracellular signaling, and deregulation of this signal can have adverse consequences for cellular responses, often leading to diseases such as diabetes and cancer.

PtdIns-3,4,5-P₃-Binding Proteins

The mechanism by which PI 3-K activates downstream secondary signaling pathway is by the recruitment of cytosolic proteins to the plasma membrane at the site of PtdIns-3,4,5-P₃ production. This recruitment can have a number of consequences; in addition to causing a change in the cellular

location of the protein, it can induce a conformation change, and in the case of enzymes, it can increase (and sometimes decrease) enzymatic activity. Typically, a combination of these events results from the PtdIns-3,4,5-P₃-protein interaction. A number of protein domains have evolved, which specifically recognize phosphoinositides, particularly PtdIns-3,4,5-P₃. The first described example is the pleckstrin homology (PH) domain, a 100-amino-acid sequence found in several signaling proteins which participate in PI 3-K responses. PH domains are found in serine-threonine protein kinases (e.g., Akt/PKB and PDK-1), tyrosine kinases (e.g., Tec family kinases such as Btk), and guanine nucleotide exchange factors of small GTP-binding proteins (e.g., SOS, Grp-1, and pREX), and GTPases themselves (e.g., dynamin). In some of these cases, the PtdIns-3,4,5-P₃-protein interaction is well understood. For example, recruitment of Akt/PKB to the plasma membrane occurs in response to PtdIns-3,4,5-P₃ production. The PH domain of Akt/PKB directly binds to PtdIns-3,4,5-P₃ with high affinity and selectivity, and this leads to a conformational change in the protein kinase, which leads to unfolding of the PH domain, revealing a sequence in the catalytic domain known as the activation loop. The PDK-1 kinase, which also has a PH domain and is recruited to the membrane simultaneously with Akt/PKB, can now phosphorylate Akt/PKB at a critical threonine residue in this loop. The phosphorylated Akt/PKB is now fully catalytically competent and can itself phosphorylate downstream protein substrates. This elegant mechanism is recapitulated in a large number of other protein kinases, which are also regulated by PtdIns-3,4,5-P₃ or PDK-1, or both (e.g., protein kinase C and S6-kinases).

Recently, a distinct phosphoinositide-binding domain was described, and termed the phox (PX) domain. This 130-amino-acid domain is also found in many important signaling proteins, and was originally described in the p40^{phox} and p47^{phox} subunit of the NADPH-oxidase superoxide-generating complex in phagocytic cells. Although PX domains do not appear to bind to PtdIns-3,4,5-P₃, they bind with high affinity to PtdIns-3-P and PtdIns-3,4-P₂ and thus are important in mediating signaling downstream of these PI 3-K lipids. Another domain which has been shown to bind PtdIns-3,4,5-P₃ is the SH2 domain. Although less well understood, binding of PtdIns-3,4,5-P₃ to the SH2 domain of the phospholipase PLCγ-1, for example, leads to an increase in its enzymatic activity. Thus, several domains have evolved in higher eukaryotic cells which have the ability to bind with distinct affinities and selectivity to PtdIns-3,4,5-P₃, and other phosphoinositides. This interaction has a profound effect on downstream signaling and cellular responses.

Cellular Function

Numerous biochemical, pharmacological, and genetic studies have demonstrated that PI 3-K, and its product PtdIns-3,4,5-P₃, regulates a multitude of cellular responses. These include cell growth, protection from cell death (apoptosis), remodeling of the actin cytoskeleton, cell migration and invasion, metabolism and insulin responses, cell-cycle regulation, and gene transcription (Figure 3). It is beyond the scope of this article to discuss all of these in any detail, but some notable examples are given. Activation of the protein kinase Akt/PKB by the

PI 3-K pathway regulates cellular survival mechanisms, as well as insulin-dependent metabolism. Most proteins which mediate Akt/PKB-dependent cellular survival are inhibited by the phosphorylation event. For example, phosphorylation of the Forkhead family of transcription factors (e.g., FKHR-L1) by Akt/PKB inhibits their translocation to the nucleus due to the creation of a binding site for 14-3-3, a family of molecular chaperones. This retention of FKHR-L1 in the cytoplasm inhibits the transactivation of genes intimately associated with cell death, and the net effect is an increase in survival. Similarly, Akt/PKB phosphorylation of the pro-apoptotic protein Bad also facilitates 14-3-3 binding, and this prevents Bad from binding to the anti-apoptotic proteins Bcl-2 and Bcl-X_L, effectively preventing apoptosis. Akt/PKB can also regulate both cell-cycle progression and gluconeogenesis/glycolysis by phosphorylating glycogen synthase kinase-3 (GSK-3). This phosphorylation inhibits the elevated constitutive activity of GSK-3, which can no longer phosphorylate proteins such as Myc, the cell-cycle regulator cyclin D, and glycogen synthase. Thus, Akt/PKB signaling results in the activation of several pathways which are normally inhibited by GSK-3.

Not all PI 3-K responses are mediated by Akt/PKB. In fact, there are several other kinases which are activated by PtdIns-3,4,5-P₃ signaling, and which have important roles in cell physiology. For example, the S6-kinases, S6K-1 and S6K-2, regulate protein synthesis and insulin responses. The protein kinase C family of kinases can also be regulated by PtdIns-3,4,5-P₃-dependent mechanisms, and have been shown to mediate both cell growth and survival mechanisms, though these are not as well understood as the Akt/PKB pathway. The Tec family kinase Bruton's tyrosine kinase (Btk), which binds to PtdIns-3,4,5-P₃ via its PH domain, is important for B cell development, and importantly, genetic mutations within its PH domain have been shown to give rise to certain immunodeficiencies in humans.

Finally, regulation of the dynamics of the actin cytoskeleton is also achieved by PtdIns-3,4,5-P₃-dependent responses, and this leads to increased cell migration of many cell types (Figure 3). One important mechanism by which PtdIns-3,4,5-P₃ regulates such responses is by activating the small

GTP-binding protein Rac, known to contribute to actin remodeling and directional migration in response to chemotactic stimuli. Small GTPases, such as Rac, are activated by binding to GTP, and this is stimulated by the activation of Rac-specific guanine nucleotide exchange factors, such as SOS, Vav, and, in particular, pREX. These exchange factors have PH domains which in some cases have been shown to bind to PtdIns-3,4,5-P₃, leading to an increase in exchange activity toward Rac. In summary, the diverse cellular responses attributed to PI 3-K signaling are explained by the fact that there exist numerous signaling proteins which interact with PtdIns-3,4,5-P₃. This binding has a profound consequence on the function of the protein, leading to the activation of downstream pathways.

Glossary

Anomer Cyclic stereoisomers of saccharides with different configurations at the hemiacetal or hemiketal (anomeric) carbon. The configuration is designated as either α or β .

ATP (adenosine triphosphate) A molecule consisting of the nitrogenous base adenine linked to the sugar ribose and contains three phosphate groups attached to the ribose. ATP, present in all living cells, serves as the principal energy source of energy for cells.

cAMP (cyclic adenosine monophosphate) A cyclic form of AMP where a single phosphate is attached to both the third and fifth carbon of the ribose sugar linked to adenine. It is important in transmitting intracellular, as well as extracellular, signals induced by many agonists. cAMP binds to and activates the cAMP-dependent protein kinase (PKA).

Gluconeogenesis The synthesis of glucose from noncarbohydrate sources occurring primarily in the liver and to a small extent in the kidney. It is stimulated during starvation or intense exercise.

Glycolysis (glycolytic pathway) The anaerobic metabolism of glucose to pyruvate. This metabolism generates two

molecules of ATP and one molecule of nicotinamide adenine dinucleotide (NADH) per glucose molecule. The NADH may be used to generate energy in the form of ATP and the pyruvate may enter the tricarboxylic acid cycle to yield NADH for energy production under aerobic conditions.

GTP (guanosine triphosphate) A molecule consisting of the nitrogenous base guanine linked to the sugar ribose. The ribose contains three phosphate groups attached to the 5' carbon. GTP is another source of metabolic energy and is involved in protein synthesis and a number of signal transduction cascades.

K_m A kinetic parameter that indicates the affinity of an enzyme for its substrate and often called the Michaelis constant. It is defined as the concentration of substrate that results in half the maximal rate (V_{max}) of the enzyme-catalyzed reaction.

Protein kinase A (PKA) An enzyme that catalyzes the phosphorylation of proteins on specific serine or threonine residues in response to cAMP.

V_{max} The maximal initial velocity of an enzyme-catalyzed reaction that occurs at saturating substrate concentrations.

Discovery of PFK-2/FBPase-2

As with many discoveries, the identification of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase (PFK-2/FBPase-2) was preceded by the discovery of its product fructose-2,6-bisphosphate (F2,6BP). This sugar was first identified as the mediator responsible for stimulating hepatic gluconeogenesis. It had been known for some time that gluconeogenesis was induced in liver by elevated levels of glucagon. Emil van Shaften and Henri-Gery Hers demonstrated that rat liver lysates contained an acid-labile phosphoric ester that greatly stimulated 6-phosphofructo-1-kinase (PFK-1). The concentration of this compound in isolated hepatocytes was significantly increased by glucose and inhibited by glucagon. They then showed that this molecule was F2,6BP. Following this discovery, Hers and Uyeda identified PFK-2/FBPase-2 in rat liver as the bifunctional enzyme responsible for the generation and degradation of F2,6BP.

General Structure of PFK-2/FBPase-2

In mammalian tissues, PFK-2/FBPase-2 is a single protein with the PFK-2 activity located at the N-terminal end and the FBPase-2 located at the C-terminus. Structural analyses

demonstrate that the catalytic domains are flanked by regulatory regions at both the N and C termini. The enzyme functions as a dimer with protein-protein contacts being made at the regulatory regions at the N-terminus only. In contrast to this structure, the yeast PFK-2 and FBPase-2 enzymes are separate proteins but likely function as dimers.

Enzymology of PFK-2

While PFK-2 shares the same substrate as PFK-1, fructose-6-phosphate (F6P), the reaction catalyzed by PFK-2 differs from that catalyzed by PFK-1 in four important aspects. First, PFK-1 catalyzes the transfer of the γ -phosphate of adenosine triphosphate (ATP) to carbon-1 (C-1) of F6P generating F1,6BP while PFK-2 catalyzes the transfer of this ATP phosphate to C-2 yielding F2,6BP. Second, PFK-1 prefers the α -anomer of F6P, while PFK-2 prefers the β -anomer. Third, PFK-1 is strongly inhibited by ATP while PFK-2 is not sensitive to this nucleotide. Finally, PFK-2 is inhibited by both of its products, adenosine diphosphate (ADP) and F2,6BP, which are activators of PFK-1.

The complete catalytic mechanism of PFK-2-mediated phosphorylation of F6P has not been elucidated. Important features of the reaction have, however, been identified. In general, PFK-2 activity is much weaker than that of PFK-1.

This may be due to the fact that specific residues involved in accelerating catalysis in PFK-1 are absent in PFK-2. The pH optimum of the enzyme-catalyzed reaction is between 8 and 9, requires magnesium, and prefers ATP as the phosphate donor but uses guanosine triphosphate (GTP). Inhibition studies indicate that the PFK-2-mediated transfer of phosphate from ATP to F6P occurs via a sequential-ordered mechanism with ATP binding prior to F6P binding. Binding sites for ATP and F6P have been identified besides residues critical for catalysis.

Enzymology of FBPase-2

Much more is known about the reaction mechanism used for FBPase-2-mediated hydrolysis. The enzyme has a pH optimum between 5.5 and 6.5 and does not require any divalent cations. FBPase-2 specifically hydrolyzes the phosphate on C-2 of F2,6BP and will not hydrolyze C-6 of either F2,6BP, F1,6BP, or glucose-1,6-bisphosphate. It is, however, inhibited by both its substrate and product: F6P and F2,6BP. Interestingly, the FBPase-2 reaction mechanism involves an intermediate in which F6P is covalently bound to a histidine residue on the enzyme. This covalent intermediate has been useful in structural studies designed to elucidate the reaction mechanism which appears to resemble, but is not identical to, the mechanism used by serine proteases. Both involve a catalytic triad in which three residues work together to form an intermediate in which the substrate is covalently bound to the enzyme followed by hydrolysis of this intermediate to release the product from the enzyme. In the case of serine proteases a serine residue on the enzyme is covalently bound to the catalytic intermediate, whereas in FBPase-2 a phosphohistidine is formed and F6P is released. The dissociation of the F6P product appears to be the rate-limiting step.

Isoforms of PFK-2/FBPase-2

Since the discovery of PFK-2/FBPase-2 in mammalian tissues, a number of mammalian isoforms have been identified from four genes which include alternatively spliced products. In all isoforms, the catalytic domains are highly conserved while the N and C termini are most divergent. Most tissues contain varying amounts of different isoforms with one isoform predominating. For example, in liver approximately 10% of the total PFK-2/FBPase-2 is the skeletal muscle isoform. Even within the predominant liver isoform, there are two different species, a 54–55-kDa species and a 58-kDa species, with only the 58-kDa species being regulated by phosphorylation (see below). In addition to these mammalian isoforms, yeast contains PFK-2 and FBPase-2 activities but in this case the enzymes are monomeric although they likely work as dimers.

In addition to sequence differences, kinetic properties of the kinase and bisphosphatase activities also differ among the various isoforms. While the substrate affinities (measured as a K_m) and maximum velocities (V_{max}) vary between isoforms, there are some notable differences. Comparison of bovine brain, liver, and testes shows that these isoforms have similar kinetic properties for PFK-2 in terms of K_m for F6P, but the liver and muscle FBPase-2 enzymes have K_m values for F2,6BP that

are approximately 100–1000-fold lower than the other isoforms. Based on V_{max} , the skeletal muscle also appears to have the lowest kinase activity and high phosphatase activity, while the placental isoform has the highest kinase activity with very little phosphatase activity.

Regulation and Physiological Roles of Specific Isoforms in Specific Tissues

PFK-2/FBPase-2 is exquisitely poised to regulate the levels of F2,6BP. F6P exerts a substrate-level control over PFK-2 and is a product inhibitor of FBPase-2. The K_m of PFK-2 and K_i of FBPase-2 for F6P are within the physiological concentration ranges of this phosphorylated sugar in different tissues, suggesting that small changes in the levels of F6P result in significant reciprocal alterations in these two enzymatic activities. Such alterations have different effects in different tissues, depending on the isoforms and relative level of the endogenous PFK-2/FBPase-2 activities.

Perhaps the best-studied form of PFK-2/FBPase-2 regulation involves the phosphorylation of the enzyme. Both the liver and heart isozymes are subject to regulation by phosphorylation. The brain isoform is phosphorylated but this phosphorylation does not appear to affect enzymatic activities. Muscle and testis isoforms are not phosphorylated. A liver isoform (58 kDa) was the first one shown to be regulated by a protein kinase A (PKA)-mediated phosphorylation stimulated by the glucagon-induced second messenger cyclic adenosine monophosphate (cAMP). Further studies showed that PFK-2/FBPase-2 is phosphorylated on a specific serine residue, serine-32, near the N-terminus. This phosphorylation leads to inhibition of PFK-2 and activation of FBPase-2. For PFK-2 at physiological pH, this is primarily due to an increase in the K_m (i.e., lower affinity) for F6P, without affecting the K_m for ATP, and only slightly perturbing V_{max} . In contrast, this phosphorylation activates FBPase-2 by increasing the V_{max} of the enzyme without affecting the K_m for F2,6BP. It is believed that this effect is largely due to an increase in the rate of F6P dissociation from FBPase-2 which enhances the rate at which the phosphohistidine intermediate is hydrolyzed. Consistent with the critical role of this enzyme in regulating liver carbohydrate metabolism, phosphorylation of the enzyme can be reversed by specific, regulated protein phosphatases (protein phosphatase 2A and 2C) which serves to activate PFK-2 while inhibiting FBPase-2. On the other hand, phosphorylation of the heart isoform modulates only the PFK-2 activity without affecting FBPase-2. Importantly, in stark contrast to the liver isoform, phosphorylation of the heart isoform activates PFK-2. In bovine and rat hearts, phosphorylation lowers the K_m (i.e., increases the affinity) for F6P. The bovine heart isoform may be phosphorylated by PKA and the rat heart isoform can be phosphorylated and modulated by either PKA or the calcium/calmodulin-dependent protein kinase.

The fact that PFK-2 and FBPase-2 are located near the N and C termini respectively on the same polypeptide begs the question as to how both activities of the liver enzyme are affected by a phosphorylation near the N-terminus. While the exact mechanism underlying the reciprocal regulation of these two activities has not been resolved, a current view is that in the

Figure 1 Reciprocal regulation of dimeric PFK-2/FBPase-2 in liver by phosphorylation. The blue indicates the N-terminal region containing PFK-2 activity and the red indicates the C-terminus containing the FBPase-2 activity. The triangle at the N-terminus and the pentagon at the C-terminus represent regulatory regions.

nonphosphorylated state, the N-termini of two polypeptides interact and activate the kinase while the C-terminal regions are separated (Figure 1). This is consistent with the crystal structure of the rat testis PFK-2/FBPase-2. Phosphorylation is believed to induce a conformational change in the enzyme resulting in the separation of the N-termini which inactivates the kinase while activating the phosphatase.

The above regulation provides for short-term, acute regulation for rapid, transient responses. The enzyme is also subject to long-term regulation mediated by gene expression. Insulin and dexamethazone both stimulate an increase in the level of PFK-2/FBPase-2 gene expression. Consistent with this, levels of liver PFK-2/FBPase-2 are depressed during starvation or diabetes and increase upon re-feeding or administration of insulin, respectively. In addition, levels of PFK-2/FBPase-2 decrease following partial hepatectomy and increase during liver regeneration.

The differences in isoforms and their regulation suggest different roles for each isoform. This is most dramatically seen when comparing the regulation of the liver isoform with that of the heart isoform. Liver not only consumes energy, but also stores energy mainly in the form of glycogen. It is also the only tissue, besides kidney to a small extent, which engages in gluconeogenesis to supply glucose to other glucose-dependent tissues in times of need. In that, as previously mentioned, the liver isoform is exquisitely poised to reciprocally regulate the level and activities of PFK-2/FBPase-2. This regulation is sensitive to glucose levels or hormones involved in regulating carbohydrate metabolism such as insulin (which stimulates glycolysis) and glucagons (which induces gluconeogenesis). On the other hand, heart muscle is a constant energy-consuming tissue and, therefore, engages in glycolysis but not gluconeogenesis. Indeed, the heart does not respond to glucagon but does respond to another hormone that signals through PKA, epinephrine. It is not surprising, therefore, that the regulated heart isoform of PFK-2/FBPase-2 responds to phosphorylation

by increasing PFK-2 activity as this hormone would signal a need for increased glycolytic flux. The increased PFK-2 activity would lead to an increase in F2,6BP levels, thereby increasing glycolysis via activation of PFK-1. The regulation of liver and heart isoforms exemplifies how differential regulation of specific isoforms can serve different roles, depending on the needs of various tissues in which they are expressed. This further illuminates the significant role PFK-2/FBPase-2 plays in appropriately regulating carbohydrate metabolism.

The role of PFK-2/FBPase-2 in pancreatic beta cells is much less clear. The isoform in these cells is similar to that found in the heart. The pancreatic beta cells release insulin in response to glucose. It has long been recognized that this release is at least in part regulated by the metabolism of glucose. The first regulated step in the metabolism of glucose is its phosphorylation catalyzed by an isoform of the enzyme hexokinase. Interestingly, the pancreatic isoform of PFK-2/FBPase-2 may exert an effect on insulin secretion by its effect on the hexokinase in these cells, also called an isoform of glucokinase. This effect may be independent of either PFK-2/FBPase-2 enzymatic activities establishing yet another mechanism through which this diverse and interesting enzyme affects glucose metabolism and homeostasis.

Glossary

Inositol A six-carbon cyclic alcohol with hydroxyl residues present at each carbon.

Kinase An enzyme that catalyzes the transfer of a phosphate group from adenosine triphosphate to a second substrate.

Phosphatase An enzyme that hydrolyzes a phosphate group from a substrate.

Phosphoinositide A phospholipid molecule composed of inositol and diacylglycerol.

Phosphoinositides are one of the many phospholipid families found within membrane bilayers of eukaryotic cells. Site-specific phosphorylation of phosphoinositides by lipid kinases results in the generation of multiple phosphatidylinositol phosphate isomers. These mono- or poly-phosphorylated isomers either can be further modified by additional enzymes or can directly modulate numerous cellular functions. Because of the potential for phosphoinositides to alter a variety of cellular processes, their synthesis must be strictly regulated. A number of phosphoinositide kinases and phosphatases have been identified and characterized. By adding or removing phosphate groups at specific positions along the inositol ring, these kinases and phosphatases dictate the signaling capacity of phosphoinositides.

Phosphoinositides

Structure

The basic structure of phosphoinositides consists of a six-carbon inositol ring linked by a phosphodiester bond to diacylglycerol (DAG) (Figure 1). The two fatty acid tails of the DAG moiety anchor phosphoinositides into the various membrane structures throughout eukaryotic cells, such as the endoplasmic reticulum (ER), Golgi apparatus, and plasma membrane. *In vivo*, phosphoinositides can be phosphorylated at the 3-, 4-, and 5-hydroxyl positions along the inositol ring in all possible combinations.

Nomenclature

Phosphatidylinositol (PI) is the initial substrate for a number of phosphoinositide kinases that phosphorylate the hydroxyl groups along the inositol ring. Mono- and polyphosphorylated phosphoinositides are named with respect to the positions of the inositol ring that are phosphorylated. Phosphorylation of PI at the 4-hydroxyl position generates PI 4-phosphate (PI4P); a subsequent phosphorylation at the 5-hydroxyl position generates PI 4,5-bisphosphate (PI(4,5)P₂). PI can be singly or severally phosphorylated at the 3-, 4-, and 5-hydroxyl positions to yield PI mono-, bis-, or trisphosphate molecules.

PI 4-Kinases

Subfamilies

PI 4-kinases use PI as a substrate to generate PI4P. PI 4-kinases are classified as either type II or type III kinases based on their structural and kinetic properties. Two mammalian isoforms termed α and β have been identified for each PI 4-kinase subfamily. Type III PI 4-kinases are structurally and kinetically similar to PI 3-kinases. PI 3-kinases and type III PI 4-kinases have homologous catalytic domains, and type III PI 4-kinases are even inhibited by known PI 3-kinase inhibitors, such as wortmannin. Type II PI 4-kinases do not share these structural or catalytic similarities with PI 3-kinases.

Cellular Functions

The higher-order species such as PI(4,5)P₂ and PI(3,4,5)P₃ have received significant attention, whereas PI4P has typically been thought of simply as a metabolic intermediate in the synthesis of other phosphoinositides. However, a number of functional studies have demonstrated important roles for PI 4-kinases *in vivo*. Type II PI4-kinases have been linked to roles in both secretion and endocytosis. Type III PI4-kinases have been most thoroughly characterized in the budding yeast *Saccharomyces cerevisiae*. Stt4 and Pik1, the yeast homologs of mammalian type III α - and β -isoforms, respectively, are targeted to distinct subcellular locations and perform nonredundant functions. Pik1 is targeted to the nucleus and Golgi. The nuclear function of Pik1 is unknown, but several studies have indicated that Pik1 is required for normal secretion from the Golgi. PI 4-kinase β , the mammalian homolog to Pik1, has also been implicated in Golgi function. Stt4 localizes primarily to the plasma membrane and ER and has been linked to actin cytoskeleton organization and cell wall stability. The PI4P generated specifically by Stt4 can be further phosphorylated by Mss4, the yeast homolog of type I PI phosphate kinases, or dephosphorylated by the phosphoinositide phosphatase Sac1. The interplay between Stt4, Mss4, and Sac1 controls actin dynamics in *S. cerevisiae*. As mentioned above, Pik1 and Stt4 are functionally nonredundant. A loss of activity in either PI 4-kinase causes a unique phenotype that cannot be rescued by increasing the activity of the other kinase. These observations suggest that Pik1 and Stt4 each generate

Figure 1 Phosphoinositide structure. Phosphoinositides are comprised of a six-carbon inositol ring linked by a phosphodiester bond to diacylglycerol. The inositol ring is numbered counterclockwise starting at the phosphodiester linkage. *In vivo*, phosphoinositides are phosphorylated at the 3, 4, and 5 positions of the inositol ring; phosphatidylinositol 4,5-bisphosphate (PI(4,5)P₂) is pictured.

discrete pools of PI4P at different subcellular locations, and that these pools of PI4P are utilized by unique sets of effectors.

PI Phosphate Kinases

PI phosphate kinases (PIP kinases) generate PI bisphosphate (PIP₂) from PI monophosphate isomers. PIP kinases are classified into type I, II, or III subfamilies based on their structural and kinetic properties. Members of all three subfamilies have highly conserved kinase domains toward the C-terminus of the proteins, with more variable flanking sequences. Each PIP kinase subfamily has unique substrate specificity dictated by a region at the C-terminal end of the kinase domain named the activation loop. The activation loop is nearly identical for different isoforms within a subfamily but divergent between subfamilies (Figure 2).

Type I PIP Kinases

Type I PIP kinases are PI4P 5-kinases, that is, they use PI4P as a substrate to generate PI(4,5)P₂. Three mammalian type I PIP kinase isoforms termed α , β , and γ have been identified. These isoforms share a highly conserved kinase domain with variable amino and carboxy termini. The variable regions regulate enzymatic activity and direct the subcellular localization of each

Figure 2 PIP kinase structure and the activation loop. The crystal structure for the human type II β PIP kinase isoform is shown above with PI5P modeled into the active site. Although the activation loop was not resolved in the crystal structure, its position relative to the active site is illustrated. A sequence alignment of type I, type II, and type III PIP kinase activation loops is shown below the crystal structure. The activation loop is highly conserved among members of each subfamily but divergent between subfamilies. Hu, human; Sp, *S. pombe*; Sc, *S. cerevisiae*; Dm, *D. melanogaster*; Ce, *C. elegans*.

isoform through unique protein–protein interactions. These three isoforms also have alternatively spliced forms, further enhancing the diversity of targeting for these kinases. Type I PIP kinases are best known for their ability to alter the organization of the actin cytoskeleton. PI(4,5)P₂ regulates the activity of many proteins that process actin at the plasma membrane. Mss4, the yeast homolog of mammalian type I PIP kinases, is required for proper actin cytoskeleton organization and cell wall integrity. Yeast lacking Mss4 activity can be rescued by expressing mammalian type I PIP kinase isoforms, illustrating that type I PIP kinases are functionally conserved in eukaryotes. Mammalian type I PIP kinases localize to sites of cortical actin dynamics, such as lamellipodia and focal adhesions, and

modulate the assembly of these structures in a PI(4,5)P₂-dependent manner. The type I γ isoform is targeted to focal adhesions by an association with the protein talin and is tyrosine phosphorylated in a focal-adhesion-kinase (FAK)-dependent manner. Kinase-dead PIP kinase I γ mutants block focal adhesion assembly, reinforcing the requirement for PI(4,5)P₂ in focal adhesion signaling. Additional roles for the I γ isoform have also been recently demonstrated in clathrin-mediated endocytosis and trafficking and assembly of E-cadherin (a transmembrane cell-cell adhesion protein) adherens junctions. More recently, a splice variant of the I α isoform has been shown to have an important role in the regulation of messenger RNA (mRNA) processing in the nucleus.

Type II PIP Kinases

Type II PIP kinases are PI5P 4-kinases, generating PI(4,5)P₂ from PI5P in a catalytically distinct reaction from type I PIP kinases. Like type I PIP kinases, the type II subfamily is comprised of α -, β -, and γ -isoforms, with the II α isoform being the most catalytically active. In contrast to the well-described physiological functions for type I PIP kinases, *in vivo* functions for type II PIP kinases remain largely undefined. Although type I and type II PIP kinases both produce PI(4,5)P₂, the two subfamilies are functionally nonredundant. No homologs for mammalian type II PIP kinases have been identified in *S. cerevisiae*, so type II PIP kinases may have specialized functions in higher eukaryotes. One such function could be to modulate receptor-mediated signaling, as the type II β isoform has been identified in a complex with the p55 TNF α transmembrane receptor. Alternatively, the II γ isoform is thought to be involved in regulation of vesicular trafficking from the Golgi apparatus. Interestingly, the II α and II β isoforms have been shown to heterodimerize, resulting in targeting of the II α isoform to both the cytoplasm and the nucleus. Recent work has identified a novel role for the II β isoform in the regulation of nuclear stress response signaling pathways. Downregulation of a pool of nuclear II β following cellular stress causes the accumulation of PI5P in the nucleus, which induces pro-apoptotic signaling by activating both the tumor suppressor p53 and p38 MAP kinase stress response pathways. Interestingly, PI5P, not PI(4,5)P₂, appears to be the potent signaling molecule in this system, and a key function for nuclear II β under nonstressed conditions appears to be the removal of nuclear PI5P via its conversion to PI(4,5)P₂.

Type III PIP Kinases

Type III PIP kinases are PI3P 5-kinases, generating PI(3,5)P₂ from PI3P. The *S. cerevisiae* protein Fab1 was the first type III PIP kinase to be identified. In yeast, Fab1 and PI(3,5)P₂ are involved in vacuole morphology, membrane trafficking, and stress response. Type III PIP kinases were not initially identified in mammalian cells, and *in vitro* studies suggested that type I isoforms can generate PI(3,5)P₂ and thus may perform similar functions to those of Fab1 in yeast. More recently, however, proteins homologous to ScFab1 have been identified in mammalian cells. PIKfyve (phosphoinositide kinase for five position containing a Fyve finger) is one example. These mammalian enzymes have similar *in vivo* substrate specificity to

the *S. cerevisiae* Fab1 enzyme and appear to regulate membrane trafficking in a manner comparable to ScFab1. Surprisingly, PIKfyve has been shown to phosphorylate PI to form PI5P *in vitro*, providing a putative mechanism for the direct synthesis of PI5P *in vivo* (as opposed to generation via dephosphorylation of higher order phosphoinositides).

PI Phosphatases

PI phosphatases are enzymes that can selectively dephosphorylate both lipid phosphoinositides and soluble inositol polyphosphates. As a family, they can be subdivided by their catalytic properties and substrate specificity.

Phosphoinositide 4-Phosphatases

The phosphoinositide 4-phosphatases (inositol polyphosphate 4-phosphatases) are a family of enzymes that dephosphorylate the 4-position of the inositol ring in a magnesium-independent manner. The members of this family can utilize PI(3,4)P₂, Ins(3,4)P₂, and Ins(1,3,4)P₃ as substrates *in vitro*, generating PI3P, Ins3P, and Ins(1,3)P₂, respectively (though Ins(3,4)P₂ and Ins(1,3,4)P₃ are dephosphorylated to a much lesser extent). Two genes have been identified in humans corresponding to type I and type II 4-phosphatases. These genes can be alternatively spliced, resulting in expression of several variant phosphatases (type I α and I β and type II α and II β isoforms, with the β isoforms expressed with hydrophobic C termini). Both types share a 37% total sequence identity and a conserved CKSAKDRT consensus sequence. This C-X₅-R consensus sequence is consistent with other magnesium-independent phosphatases.

Cellular Functions of 4-Phosphatases

The PI-3 kinase (PI3K) signaling pathway impacts cell growth, glucose metabolism, and apoptosis. Activation of the PI3K pathway results in the generation of PI(3,4,5)P₃ and PI(3,4)P₂, which stimulate downstream effectors such as protein kinase B/Akt and PI3K-dependent kinase 1. Phosphoinositide 4-phosphatases are thought to participate in regulation of the PI3K pathway by converting PI(3,4)P₂ to PI3P, thus attenuating the PI3K signal and subsequently deactivating PI3K effectors. An association identified between a PI 4-phosphatase and the PI3K p85 regulatory subunit supports this putative function for PI 4-phosphatases. Recently, the type I α isoform has been implicated in regulation of megakaryocyte and fibroblast proliferation, in addition to modulating PI3K signaling in endosomes and at the plasma membrane.

Phosphoinositide 5-Phosphatases

Phosphoinositide 5-phosphatases (inositol polyphosphate 5-phosphatases) dephosphorylate the 5-position of the inositol ring in a magnesium-dependent manner. This family collectively can utilize four substrates: PI(4,5)P₂, PI(3,4,5)P₃, Ins(1,4,5)P₃, and Ins(1,3,4,5)P₄. PI 5-phosphatases contain a bipartite consensus sequence, (F/I)WXGD_XN(F/Y)R, followed several amino acids downstream by (R/N)XP(S/A) (W/Y) (C/T)DR(I/V) (L/I). PI 5-phosphatases are classified into four groups based on their substrate specificity.

Group I 5-Phosphatases

Group I 5-phosphatases use $\text{Ins}(1,4,5)\text{P}_3$ and $\text{Ins}(1,3,4,5)\text{P}_4$ as substrates. Type I 5-phosphatase, one member of this group, is thought to play a role in the regulation of cellular calcium levels. $\text{Ins}(1,4,5)\text{P}_3$ (IP_3) is a pivotal regulator of cellular calcium levels and is generated by the cleavage of PIP_2 by phospholipase C. The resulting IP_3 binds to the IP_3 receptor, triggering a release of calcium ions from intercellular stores. Type I 5-phosphatase decreases this signal by dephosphorylating IP_3 into $\text{Ins}(1,4)\text{P}_2$.

Group II 5-Phosphatases

Members of group II 5-phosphatases can utilize all four of the substrates mentioned above. The synaptojanins, type II 5-phosphatase (INPP5B), and the oculocerebrorenal syndrome of Lowe (OCRL) gene product, OCRL-1, are all members of this group. In total, nine variants have been described in humans. OCRL is an X-linked disorder resulting in mental retardation, renal dysfunction, and congenital cataracts. Although the pathogenesis for these symptoms is not currently known, OCRL-1 dysfunction results in an increase in $\text{PI}(4,5)\text{P}_2$ levels, as observed in cells cultured from individuals with this disorder. Interestingly, OCRL-1 shares 51% identity with type II 5-phosphatase. However, this enzyme cannot compensate for the lack of OCRL-1 activity, possibly due to a difference in substrate specificity or tissue localization. OCRL-1 does contain a Rho-GAP (guanosine triphosphatase-activating protein) domain, which facilitates its targeting to the *trans*-Golgi network via interaction with the small G-protein Rac. The synaptojanins, on the other hand, have functions distinct from OCRL-1 and type II 5-phosphatase. These proteins contain N-terminal SAC1 domains, homologous to the yeast Sac1p phosphoinositide phosphatase. Synaptojanin 1 has been shown to function in recycling of vesicles at neuronal synapses and it has also been linked as a candidate gene to bipolar disorder. Synaptojanin 2, on the other hand, has been shown to be required for clathrin-coated pit formation and has been shown to be involved in cell migration via regulation of lamellipodia formation. This protein is alternatively spliced and some variants have been shown to have functions overlapping that of synaptojanin 1, while other variants have been localized to distinct cellular compartments, such as the outer mitochondrial membrane.

Group III 5-Phosphatases

Group III 5-phosphatases are active toward $\text{PI}(3,4,5)\text{P}_3$ and $\text{Ins}(1,3,4,5)\text{P}_4$, which have a 3-position phosphate group. Src homology domain containing inositol phosphatases (SHIPs), SHIP1 and SHIP2, are important members of this group. These proteins share 50% sequence identity and similar

substrate specificity, but differ in their tissue expression levels. SHIP1 is primarily expressed in hematopoietic tissues while SHIP2 is expressed in nonhematopoietic tissues. Recent work has demonstrated an importance of SHIPs in signal transduction. SHIP2 has been shown to associate with specific tyrosine kinase receptors, such as the EGF receptor. This places the phosphatase in an ideal location to attenuate the increased $\text{PI}(3,4,5)\text{P}_3$ and $\text{PI}(3,4)\text{P}_2$ levels generated by PI3K, which is also recruited to these receptors. SHIP2 mouse knockout experiments support SHIP2's role in PI3K signal termination and also suggest a link between SHIP2 activity and insulin resistance, a primary factor in type 2 diabetes.

Group IV 5-Phosphatases

Group IV phosphatases are the least characterized of the four groups. One member, phosphoinositide 5-phosphatase type IV (INPP5E) in humans or pharbin in rats, has been identified. This phosphatase utilizes $\text{PI}(3,4,5)\text{P}_3$ as its primary substrate, and has also been shown to dephosphorylate $\text{PI}(4,5)\text{P}_2$ and $\text{PI}(3,5)\text{P}_2$. Expression levels are highest in the brain for both humans and mice, with lower expression in other tissues. This phosphatase has been implicated in glucose metabolism and control of food intake.

Glossary

Kinase An enzyme that catalyzes the transfer of a phosphate group from ATP onto another molecule.

Phosphatase An enzyme that catalyzes the hydrolytic removal of phosphate from another molecule and its release as free phosphate.

Phosphoinositide A phospholipid in which the polar head group is inositol or a phosphorylated derivative of inositol.

The cells of multicellular organisms respond to external stimuli, such as growth factors, cytokines, neurotransmitters, and many hormones, through regulated changes in the levels of cellular signaling molecules, termed second messengers. The inositol phospholipids (collectively known as phosphoinositides) are constituents of cell membranes that play important roles as second messengers in signal transduction and membrane trafficking. Many of the downstream effects of phosphoinositide signaling are mediated through reversible protein phosphorylation and in this article the principal focus is upon protein kinases that function as downstream targets of the phosphoinositide 3-kinase (PI 3-kinase) lipid signaling pathway.

Phosphoinositide Signaling – An Overview

Phosphoinositides are a small family of differentially phosphorylated membrane-localized lipid second messengers. These lipids comprise the hydrophilic cyclic polyol, myo-inositol (Ins), linked via a diester phosphate in the 1-position to diacylglycerol, the hydrophobic membrane anchor. Several families of lipid kinases and phosphatases selectively insert and remove monoester phosphates in three of the remaining positions of the inositol ring, generating the eight currently known phosphoinositide species. This article focuses on some of the most intensively studied phosphoinositide signaling pathways initiated when growth factors, cytokines or insulin, and related hormones trigger the activation of one or more of the type I PI 3-kinases. These enzymes phosphorylate a small proportion of the cellular phosphatidylinositol 4,5 bisphosphate (PtdIns(4,5)P₂) to generate PtdIns(3,4,5)P₃ (often abbreviated to PIP₃). The latter is further metabolized by 5-phosphatases to PtdIns(3,4)P₂ or is returned to the PtdIns(4,5)P₂ pool by the tumor-suppressor lipid phosphatase PTEN. PtdIns(3,4,5)P₃ activates downstream signaling through proteins which possess a phosphoinositide binding domain capable of distinguishing this target lipid within a membrane that contains at least 100-fold higher levels of the parent lipid PtdIns(4,5)P₂. Several modular protein domain families have now been identified that include members able to bind to specific phosphoinositides, such as pleckstrin homology (PH), Phox homology (PX), FYVE, and ENTH domains.

Other domains, such as FERM, and PDZ domains may also function as phosphoinositide-binding motifs, although evidence for their selectivity between different phosphoinositides is currently lacking. In almost all cases presently identified, the PtdIns(3,4,5)P₃-specific-binding motifs mediating PI 3-kinase-dependent signaling are members of the PH domain family.

Protein Kinase B/Akt

Since the 1990s, it has become evident not only that PI 3-kinase signaling plays a pivotal role in regulating many diverse and significant cellular processes, including cellular proliferation, survival, size, and motility, but also that many of the downstream effectors of PtdIns(3,4,5)P₃ are protein kinases. The best evidence for regulation by PtdIns(3,4,5)P₃ exists for three classes of kinases that carry PH domains able, specifically, to bind this lipid: the Ser/Thr kinases, PKB (or Akt), PDK1, and the Tec family Tyr kinases. Space limitations prevent us from addressing enzymes such as GSK3 or PAK, which can clearly be regulated by the PI 3-kinase pathway, though not by directly binding to PtdIns(3,4,5)P₃, and these enzymes can also be regulated by PI 3-kinase-independent pathways. The PI 3-kinase signaling pathway has been dissected extensively using biochemical and genetic approaches. Significantly, the stimulated production of PtdIns(3,4,5)P₃ by PI 3-kinase enzymes is conserved in species from slime molds, through nematodes and flies to vertebrates. In species of all of these groups, genetic studies indicate that a principal (though not exclusive) cellular mediator of this signaling pathway is protein kinase B (PKB).

PKB, also known as Akt, has a C-terminal serine/threonine kinase domain and an N-terminal PH domain that binds with high specificity to PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂. The enzyme has been shown to be activated by phosphorylation of two key residues, threonine 308, in the activation loop (or T-loop) of the kinase domain, and serine 473 in the C-terminal tail. These phosphorylation events in turn are believed to alter the conformation of PKB, greatly enhancing its activity, and although much of this work has focused on PKB, it now appears that a number of related kinases may be regulated by analogous mechanisms. Although PtdIns(3,4,5)P₃ and

PI(3,4)P₂ do not directly enhance the activity of PKB *in vitro*, they play a critical role in the phosphorylation and activation of PKB, by recruiting PKB to the plasma membrane where it is activated, and by opening the conformation of the protein to allow phosphorylation. Thus, it seems that in a normal cellular context, the activity state of PKB is largely governed by cellular levels of PtdIns(3,4,5)P₃ and PI(3,4)P₂.

PDK1 and the Regulation of the AGC Kinases

3-Phosphoinositide-dependent kinase 1 (PDK1) has been identified as the activating kinase that phosphorylates PKB in a PI 3-kinase dependent process at Thr 308 *in vitro* and *in vivo* (see Figure 1). This protein serine/threonine kinase also has a PH domain that specifically binds PtdIns(3,4,5)P₃ and PI(3,4)P₂ and is found both in the cytosol and on the plasma membrane. Significantly, after its initial identification as a PKB kinase, subsequent work has shown that it also phosphorylates and activates many other related kinases. A point of current controversy is whether the function of PDK1 itself is regulated through mechanisms such as phosphorylation or translocation to the plasma membrane. It has been proposed that PDK1 translocates to the plasma membrane in response to stimulated rises in cellular PtdIns(3,4,5)P₃ levels, as does PKB. However, this conclusion is not supported by other work, and as PDK1 has an affinity approximately 10-fold greater for these lipids than does PKB, an alternative idea is that a pool of cellular PDK1 may be constitutively associated with the plasma membrane and that its activity is not normally regulated by changes in the levels of these lipids. It has also been proposed that PDK1 is activated in stimulated cells by tyrosine

phosphorylation, possibly by a Src family kinase, although, once more, other work argues against this, and phosphorylation has not been observed in response to physiological stimuli, or in cells expressing physiological levels of the relevant kinases. Most of this work on the regulation of PDK1 function would suggest that if it is to be viewed as a phosphoinositide-regulated kinase, this regulation occurs through direct or indirect effects of PtdIns(3,4,5)P₃ on its substrates, rather than on PDK1 itself.

PKB exists as three isoforms in human cells (PKB α , β , and γ), but is itself a part of a diverse structurally related family of protein kinases, which are phosphorylated by PDK1 at a residue in the T-loop of each kinase. Although this PDK1-mediated phosphorylation plays a role in the activation of each of these kinases, in contrast to PKB, the phosphorylation of other family members is not directly responsive to cellular PtdIns(3,4,5)P₃ levels, and alternative signaling inputs seem to be required to activate these other kinases strongly. To allow efficient activation, most of these related kinases require the interaction of a hydrophobic motif, positioned C-terminal to their kinase domain, with a hydrophobic pocket on PDK1. In some cases, for example, S6K1 and SGK, this hydrophobic motif contains a serine or threonine that must be phosphorylated to allow interaction with and activation by PDK1. In these cases, it appears that this phosphorylation is in turn mediated by an unknown PI 3-kinase-dependent kinase. In contrast, in place of this serine or threonine residue, PKC ζ and PRK2 have an acidic residue, which appears to mediate phosphorylation-independent interaction with, and activation by, PDK1. PKC ζ , and probably the other atypical PKC kinases, PKC ι and PKC λ , are also unusual in that there is some evidence for the direct activation of the kinase through interaction with PtdIns(3,4,5)P₃.

Figure 1 Mechanism of activation of PKB, mTOR, and S6K1 by PI 3-kinase. A model is shown for the activation of downstream kinases by a transmembrane receptor activating PI 3-kinase. Molecules are shown in the stimulated conformation. In unstimulated cells, PI 3-kinase is less active, PIP₃ levels are low, PKB is cytosolic, and along with TSC2 and S6K1, is unphosphorylated and inactive. Active TSC2 promotes the conversion of GTP to GDP by Rheb, although the mechanism by which this leads to the activation of mTOR signaling is unclear. Direct phosphorylation events are shown by bold arrows and indirect mechanisms of activation are represented by dotted arrows. Phosphates are represented by a circled letter P.

However, these kinases lack a PH domain or other identified PtdIns(3,4,5)P₃-binding motif, and the mechanism and physiological relevance of this apparent activation is unclear.

PDK2 – The Unidentified Hydrophobic Motif Kinase

The term PDK2 was used originally to describe the unidentified kinase responsible for the phosphorylation of PKB at the hydrophobic motif serine 473. Since then, although several candidates have been proposed, such as ILK, MAPKAP-K2, NEK6, and both PKB and PDK1 themselves, the identity of PDK2 is still not clear. What is clear, however, is that most of the AGC family kinases become phosphorylated at a serine or threonine residue in a hydrophobic motif C-terminal to the kinase domain, and that this phosphorylation plays a critical role in the activation of each enzyme. It is quite possible that different PDK2s exist for different AGC family kinases; it appears that a substantial component of the PI 3-kinase-dependent activation of kinases, such as SGK and S6K1, may be mediated by an as-yet unknown phosphoinositide-dependent hydrophobic motif kinase. As a consequence of the mechanisms of activation of this family of kinases, increases in cellular PtdIns(3,4,5)P₃ levels seem sufficient to activate PKB, since PtdIns(3,4,5)P₃ and PH domain-dependent colocalization of PKB and PDK1 appears to be the principal mechanism of regulation of this kinase. In contrast, most other PDK1-regulated kinases seem to require regulated docking with PDK1 through a protein–protein interaction to mediate activation in the cytosol, and it is this docking step that may be regulated by different upstream pathways, some of which may themselves involve phosphoinositide-dependent kinases.

Much of the interest in PKB stems from its role in mediating many of the effects of PI 3-kinase activation. Evidence now indicates that a substantial portion of the effects of elevated PtdIns(3,4,5)P₃ levels on cell-cycle progression, survival, growth, and insulin responses are mimicked by activation of PKB alone. In contrast, most PI 3-kinase-dependent cytoskeletal regulation appears to be PKB independent, but may rather result from the interaction of PtdIns(3,4,5)P₃ with the PH domains of guanine–nucleotide-exchange factors for Rho family GTPases. These findings go some way to explain why isoforms of PKB have been found to be overexpressed in a range of human tumor types, and why activation of PKB activity appears to be an even more common feature of tumors.

Regulators of Cellular Growth – mTOR and S6K1

Work addressing the stimulation of cell growth by PtdIns(3,4,5)P₃ signaling implicates two protein kinases as key players in this process, the mammalian target of rapamycin (mTOR), and ribosomal protein S6 kinase 1 (S6K1, also known as p70S6K). While S6K1 seems to regulate translation through several mechanisms, mTOR has been proposed to play a central role in cellular growth control, as its activity is responsive to nutrients and ATP and is able to regulate a range of downstream processes related to cell growth, including transcription, tRNA

and ribosome synthesis, autophagy, and nutrient transporter function. Although recent work has shed significant light on the regulation of both of these kinases, particularly the inputs from PtdIns(3,4,5)P₃ signaling, their regulation appears complex and many questions remain unanswered. mTOR activity now appears to be inhibited in nongrowing cells by the small GTPase Rheb, and a protein complex of two proteins, TSC1 and TSC2, the latter of which can function as a GTPase-activating protein for Rheb. Upon activation of PI 3-kinase and PKB, TSC2 is phosphorylated by PKB, Rheb becomes inactive (in the GDP bound state) causing activation of mTOR. S6K1 is then believed to be stimulated through phosphorylation by activated mTOR (in addition to other activating inputs such as PDK1). This model is represented in [Figure 1](#).

The study of S6K1, and many other kinases that are affected by PtdIns(3,4,5)P₃ signaling, with the exception of PKB, highlights a possible role for the level of basal PtdIns(3,4,5)P₃ present in unstimulated growing cells in culture. For example, S6K1 can be potently activated by G-protein-coupled receptors under conditions where PtdIns(3,4,5)P₃ levels do not increase. Thus, PtdIns(3,4,5)P₃ can play a permissive rather than stimulatory role in G-protein-coupled receptor-mediated S6K1 activation. Significantly, a similar role for basal PtdIns(3,4,5)P₃ has been proposed in the regulation of other molecules, such as Ras and PKCδ.

One important piece of evidence that cell-growth responses stimulated by mTOR and S6K1 are downstream effectors specifically of PtdIns(3,4,5)P₃ is the sensitivity of PTEN null ES cells, MEFs, and tumors to the immunosuppressant rapamycin. Deletion of the PtdIns(3,4,5)P₃ specific phosphatase, PTEN, elevates PtdIns(3,4,5)P₃ levels and activates downstream PI 3-kinase-dependent signaling without stimulating other pathways. Since these cells are unusually sensitive to growth inhibition by the mTOR (and thus S6K1) inhibitor rapamycin, this suggests that these pathways are significantly activated by increased PtdIns(3,4,5)P₃ levels, and that this is important for cell growth and tumor development.

Tec Family Kinases

The Tec family of tyrosine kinases has been implicated in signaling by lymphocyte antigen receptors. These kinases have an N-terminal PtdIns(3,4,5)P₃ binding PH domain and a C-terminal tyrosine kinase domain. They also contain a proline-rich region, and SH3 and SH2 domains in the central region of the proteins. It is believed that their activation requires recruitment to the plasma membrane by interaction of PtdIns(3,4,5)P₃ with the PH domain, and subsequent activation by members of the Src family of tyrosine kinases through phosphorylation of the kinase domain activation loop. These kinases are rather restricted in the range of tissues where they are expressed, most being hematopoietic specific, and appear to play a role most significantly in lymphocyte signaling. This picture has stemmed from the original identification of the first family member, Bruton's tyrosine kinase (Btk), as the gene mutated in a human immunodeficiency. The family is now known to include Btk, Tec, Itk, Bmx, and the slightly divergent Rlk. Interestingly, in Rlk, the PH domain has been

replaced by an N-terminal palmitoylation and membrane targeting signal, leading to PI 3-kinase-independent activation.

Perspectives

This article has focused largely upon well-studied kinases that are regulated through $\text{PtdIns}(3,4,5)\text{P}_3$ and $\text{PI}(3,4)\text{P}_2$ and the PI 3-kinase signaling pathway, and their roles in regulating cellular proliferation, survival, and growth. However, evidence for the regulation of kinases in these and other cellular signaling pathways by other phosphoinositides is emerging. For example, serum and glucocorticoid-inducible protein kinase 3 (SGK3 or CISK) is localized to endosomes through a PX-domain-mediated interaction, probably via $\text{PtdIns}(3)\text{P}$. Although tethering to endosomes appears to be required for CISK to function, there is also evidence that its catalytic activity is controlled through stimulated type I PI 3-kinases, and hence via a mechanism that also involves $\text{PtdIns}(3,4,5)\text{P}_3$. Since the human genome contains ~48 genes encoding proteins, many unstudied, with both a protein kinase domain, and a domain recognized as a potential phosphoinositide-binding domain (42 with PH domains and 6 with PX domains), it is quite possible that novel kinases, which are regulated by any of the

phosphoinositides, exist and play a role in the regulation of quite distinct cellular processes.

Glossary

Diacylglycerol (DAG) A product of phosphatidylinositol 4,5-bisphosphate (PIP₂) cleaved by phospholipase C (PLC). It serves as a second messenger activating some members of protein kinase C (PKC)s, and is readily converted to phosphatidic acid in the cell by the action of diacylglycerol kinases.

Inositol 1,4,5-triphosphate (IP₃) The other product of PIP₂ cleavage by PLC. IP₃ is a short-life second messenger. It is readily dephosphorylated by specific phosphatases or phosphorylated by the IP₃ kinase.

Pleckstrin homology (PH) domain A domain structure that occurs in a wide range of proteins involved in intracellular signaling or as constituents of the cytoskeleton.

PH was originally found in pleckstrin (platelet C-kinase substrate protein). It binds to phosphoinositides such as PIP₂ and/or PIP₃. Because of its high affinity and specificity toward PIP₂, fusion proteins of PLC- δ 1 PH domain with fluorescent protein are now widely used to monitor the location and dynamics of PIP₂ in living cells.

Src homology 2/3 (SH2/3) domain Domain structures initially identified in the protooncoprotein *src*. They facilitate protein–protein interaction and occur in various signaling proteins. SH2 domain (~100 residues) recognizes phosphorylated Tyr residues in target peptides, whereas SH3 domain (~70 residues) binds to peptide sequences rich in proline.

Phospholipase C (PLC) is an enzyme that hydrolyzes a glycerophospholipid at the phosphodiester bond between the glycerol backbone and the phosphate group. All known eukaryotic PLCs utilize only phosphoinositides (phosphatidylinositol and its phosphorylated derivatives) as substrates; hence, they are called phosphoinositide-specific PLCs and are frequently just referred to as PLC. In signal transduction, activation of PLC is one of the earliest events following binding of various agonists to cell-surface receptors, and leads to diverse and profound consequences. Upon its activation, PLC hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP₂), a minor but essential constituent of plasma membranes, to modulate numerous PIP₂-dependent cellular processes. The two PIP₂ cleavage products, inositol 1,4,5-trisphosphate (IP₃) and 1,2-diacylglycerol (DAG), are critical second messengers to mediate calcium signaling in animal cells. PLC is not a single entity but a family of isozymes with various structures. Mechanisms for regulating PLC isozymes are also diverse. To date, 13 different mammalian PLCs have been identified, and they are grouped into six subfamilies based on their primary structures.

Physiological Roles of PLC

The earliest observation of PLC action was made by Hokin and Hokin in the 1950s. They discovered that stimulation of cells could induce rapid metabolism of inositol phospholipids. In 1975, Robert Michell published a hypothesis connecting phosphoinositide breakdown and cellular calcium mobilization. Functions of IP₃ and DAG as second messengers were established in the mid-1980s by Michael Berridge and Yasutomi Nishizuka, respectively. It was these landmark discoveries that brought special attention to PLC as the key enzyme to generate the two second messengers.

The soluble part of the PIP₂ cleavage product, IP₃, binds to its intracellular receptors on the endoplasmic reticulum (ER) (calcium storage site) and causes its calcium ions to be released into the cytoplasm. The other cleavage product, DAG, stays in the plasma membrane to recruit and activate protein kinase C (PKC) isozymes. Activation of certain PKC isozymes requires binding of both DAG and calcium ions. The activated PKC elicits a wide range of cellular responses through phosphorylation of many kinds of protein substrates (Figure 1).

Besides generating second messengers, modulating the population of PIP₂ in the plasma membrane is another function of PLC, which upon its activation quickly consumes large fractions of PIP₂ pools. PIP₂ constitutes only a minor phospholipid population and it is almost exclusively present in the inner leaflet of plasma membranes. Its turnover is rapid even in resting cells, yet its cellular levels are strictly kept constant. While IP₃ and DAG function as second messengers only in animal cells, PIP₂ is essential for all eukaryotic organisms to maintain many cellular processes through its interaction with a wide variety of proteins. First, it can modify activities of various proteins, such as the membrane-acting enzyme, phospholipase D, and the membrane-embedded transient receptor potential (TRP) channels, just to name a few. Second, it provides a platform to form functional signaling complexes. Many of the proteins constituting these complexes possess PIP₂-binding modules, such as pleckstrin homology (PH), FERM (F for 4.1 protein, E for ezrin, R for radixin, and M for moesin), and epsin N-terminal homology (ENTH) domains. Thus, reduction of cellular PIP₂ directly alters metabolic or signaling status. Third, the phospholipid is a focal point at which plasma membranes are tethered to cytoskeletal networks. Therefore, spatio-temporally controlled PIP₂ turnover is a necessary step for cells to regulate their morphology and motility.

[†]Deceased.

Figure 1 A scheme for the action of PLC in the cell. For abbreviations, see text. Inset shows chemical structure of IP3.

Given such diverse and profound consequences, PLC activity is under tight regulation and its activation is a central mechanism of cellular signaling in many instances. A large number of hormones, growth factors, and neurotransmitters rely on PLC to transmit their signals across plasma membranes.

Biochemistry of PLC

Structure of PLC

PLC has been found in yeasts, slime molds, plants, and animals, and is probably present in all taxa of eukaryotes. All eukaryotic PLCs appear to be evolved from a single archetype, and it is in the animal kingdom that PLC diversified. Thirteen different genes encoding PLC isozymes have been identified in mammals, and they are grouped into six subfamilies, named as β , γ , δ , ϵ , ζ , and η (Figure 2). Animals, from nematode *Caenorhabditis elegans* to fly to human, have similar sets of isozymes, but only the primitive ζ -like PLCs are found in other eukaryotes. The protein originally termed PLC- α was later found to be a proteolytic fragment of PLC- δ 1. Some isozymes have alternatively spliced variants at the messenger RNA (mRNA) level, and the total number of mammalian PLC polypeptides exceeds 20.

All PLC isozymes possess common structural features, indicating that they were derived from a common ancestor. All nonanimal PLCs, as well as PLC- ζ , consist of, from N- to C-terminal, four copies of EF-hands, regions called X and Y, followed by a C2 domain. The δ isozymes possess a PH domain in the N-terminus in addition to the structure described above. The other four types of PLC isozymes contain additional regulatory domain(s) in addition to those shown for the δ -subtype (Figure 2). PH domains are ~ 120 -residue units, which often function as membrane-binding sites through interaction with phosphoinositides. EF-hands are the calcium-binding motifs identified in calmodulin, but it is unclear whether PLC's EF-hands actually bind calcium ions. C2 domains (~ 120 residues) are the structures originally

found in PKC as calcium-dependent lipid-binding modules. X and Y regions are unique to eukaryotic PLCs and their sequences are highly conserved. Evidence shows that the two regions together form a discrete catalytic unit, though they are separated by a linker in the primary structure.

Mechanism of Catalysis

Calcium, at the physiological intracellular ranges, is required for PLC to catalyze PIP2 hydrolysis. However, with other inositides as substrates, much higher calcium ion concentrations are needed, a condition considered to occur only in test tubes. Based on studies of the crystal structures of a PLC- δ 1-IP3 complex and other biochemical data, a catalytic mechanism has been proposed. In this mechanism, the PLC-bound calcium ion is directly interacting with the IP3 to activate the 2-hydroxy group of inositol ring that in turn attacks the 1-phosphate, and leads to the cleavage of the head group to form a 1,2-cyclic phosphate intermediate and DAG. The cyclic derivatives are subsequently hydrolyzed to acyclic inositolphosphates. The positive residues located in the active site pocket are positioned to interact with the phosphate groups at the 4- and 5-positions of the inositol ring, explaining the preference of PLC for PIP2 over phosphatidylinositol or phosphatidylinositol 4-phosphate. The structure also indicates that the pocket cannot accommodate phosphoinositides with phosphate at the 3-position (e.g., phosphatidylinositol 3,4,5-trisphosphate), explaining why 3-phosphorylated inositides are not a substrate of PLC.

The X-Y linkers of PLC isozymes vary in their length and exhibit no noticeable sequence similarities to each other, but many, if not all, of them contain clusters of acidic amino acids. A recent crystallographic study of PLC- β 2 has shown that the acidic linker is unstructured and covers the catalytic cleft, presumably blocking access for the substrates. Removal of the acidic residues resulted in creation of unregulated, constitutively active enzymes. It was thus postulated that PLCs are autoinhibited by occlusion of the active site by the X-Y linker.

Figure 2 Structural organizations of PLC isozymes. Known ligands of domains of PLCs are shown. *pY*, phosphotyrosine; Pro-rich, proline-rich sequence.

Various kinds of acidic compounds are, when incorporated into substrate vesicles/micelles, known to stimulate PLC activities *in vitro*: Perhaps electrostatic repulsion by these negatively charged chemicals could push away the acidic linker to negate the autoinhibition.

PLC Isozymes and Their Regulation Mechanisms

PLC- β

Signals of many chemical and physical stimuli are received by cells via receptors that couple to heterotrimeric G proteins. A large portion of such stimulation induces PIP₂ hydrolysis by activating PLC- β isozymes. Beta isozymes ($\beta 1 \sim \beta 4$; ~ 150 kDa) are unique in having long C-terminal extensions that are absent in other classes of isozymes (Figure 2).

Upon activation of a receptor, the receptor-associated G protein heterotrimer, $\alpha\beta\gamma$, dissociates into α - and $\beta\gamma$ -subunits. Members of α -subunits of the Gq family (α_q , α_{11} , α_{14} , and α_{16}), but not other classes of α -subunits (Gs, Gi/o, and G12/13), directly activate PLC- β . In addition, $\beta\gamma$ -complexes can also stimulate PLC- β . The α_q - and $\beta\gamma$ -subunits appear to interact with different regions in the PLC- β molecule: α_q is recognized

by the C-terminal region unique to β -isozymes, whereas the $\beta\gamma$ -subunit binds to the N-terminal PH domain. In most cells, the Gi family of G protein is abundant compared to other classes. Therefore, it is reasonable to assume that only Gi/o-coupled receptors can provide significant amounts of $\beta\gamma$, and hence agonists that induce the activation of Gi/o are responsible for $\beta\gamma$ -mediated activation of PLC- β .

It has been shown that four isozymes of this subfamily are expressed in different tissues and they exhibit different sensitivities to the G protein subunits. PLC- $\beta 1$ and $\beta 3$ are widely expressed in various tissues and are more sensitive to α_q -mediated activation relative to other isozymes. PLC- $\beta 2$ expression is restricted to blood cells and is most sensitive to the activation by $\beta\gamma$ among the four PLC- β s. It has recently been shown that Rho-family small guanosine triphosphatases (GTPases) (Rac1, Rac2, and Cdc-42, but not RhoA) are able to activate PLC- $\beta 2$ via binding to its PH-domain. PLC- $\beta 3$, but not PLC- $\beta 1$, can be activated by the small GTPases albeit weakly. PLC- $\beta 4$ expression is only seen in some parts of the brain and in the retina.

Genes for all four β -isozymes have been disrupted in mice, and none of those single knockouts appeared to be fatal, probably due to their overlap functions. However, various

phenotypes have been reported with knockouts in mice. They include: PLC- β 1, epilepsy; PLC- β 2, dysfunctions in neutrophils and platelets; PLC- β 3, hyperresponse to opioid stimulation; and PLC- β 4, ataxia and impairment in visual perception.

PLC- γ

The two isozymes of this subfamily (γ 1 and γ 2; ~140 kDa) possess a long linker sequence between the X and Y regions. The linker consists of split halves of a PH domain flanking two Src-homology 2 (SH2) domains and an Src-homology 3 (SH3) domain. SH2 domain is phosphotyrosine-containing peptide sequences, while SH3 domain interacts with proline-rich sequences. Although separated by a large insertion, halves of the split PH domain assume a canonical PH fold. The linker region also contains a Tyr residue (Tyr783 of human PLC- γ 1), which is conserved in all PLC- γ proteins in various kinds of animals and of which phosphorylation is essential for the activation (Figure 2).

One major class of stimuli to activate PLC- γ is that of growth factors, such as platelet-derived growth factor, fibroblast growth factor, and epidermal growth factor. Receptors for these growth factors are transmembrane proteins with an extracellular part to bind their cognate ligands and an intracellular part containing intrinsic protein tyrosine kinase (PTK) activity and a tail with autophosphorylation sites. Ligand binding activates the PTK, which then recruits and phosphorylates PLC- γ . The other class of receptors that lead to activation of PLC- γ is immunoreceptors found in hematopoietic cells, such as the antigen-recognizing T-cell or B-cell receptors. These receptors possess no enzymatic activity. However, they, upon ligand binding, induce the formation of supramolecular complexes composed of the receptor themselves, adaptors, and cytoplasmic PTKs. PTKs belonging to the Src-family (Lck, Fyn, etc.), the Syk-family (Syk and ZAP-70), and the Tec-family (Btk, Itk, etc.) have been implicated in PLC- γ activation.

The long X-Y linker plays a central role in the regulation of PLC- γ . Upon activation, growth factor receptors possessing intrinsic PTK activity (or the supramolecular complexes containing PTKs) undergo autophosphorylation to provide docking sites for many proteins required for the downstream signaling. PLC- γ binds these phosphotyrosine-containing docking sites via its N-terminal SH2 domain, and its conserved Tyr residue is phosphorylated by the PTK. Phosphorylated PLC- γ then expresses its otherwise autoinhibited phospholipase activity via the intramolecular interaction between the phosphorylated Tyr residue and the C-terminal SH2 domain. Thus, the two SH2 domains collaborate via different functions during the activation. Whether the split PH domain has any function beyond its apparent structural importance to organize the X-Y linker is unclear, but recent study reported that Rac small GTPases interacts with and activate PLC- γ 2, but not γ 1, via this module. Physicochemical and biochemical properties of the SH3 domain have been extensively studied. A number of proteins of diverse classes/functions have also been identified as binding partners for the SH3 domain, but the physiologic significance for many of these interactions is yet to be established.

PLC- γ 1 is expressed ubiquitously and disruption of its gene in mice is lethal at an early embryonic stage. PLC- γ 2 is expressed in a set of hematopoietic lineages including B cells,

platelets, neutrophils, and mast cells. Knockout of γ 2 is not lethal but abolishes maturation of B cells, resulting in immunodeficiency, and causes dysfunctions of Fc-receptor-mediated signaling in platelets and mast cells.

PLC- δ

PLC- δ isozymes (δ 1, δ 3, and δ 4; ~90 kDa) have simpler structures compared to other isozymes (Figure 2). The protein found as PLC- δ 2 in the cow turned out to be a homolog of PLC- δ 4 identified in humans and the mouse. The delta isozymes lack obvious regulatory domains that facilitate coupling to receptors, suggesting that they are probably not activated directly by hormone receptors. PLC- δ has greater calcium sensitivity than β - and γ -isozymes. It is feasible that PLC- δ is secondarily activated when cytoplasmic calcium concentrations are elevated, perhaps following the activation of other classes of PLC. The PH domain of PLC- δ binds to PIP2 and it can also interact with IP3 at a higher affinity: this domain is thought to mediate tethering of PLC- δ to plasma membranes. When PIP2 hydrolysis occurs, one of its products, IP3, causes dissociation of the enzyme from membranes, thus terminating the reaction. This mechanism constitutes a negative feedback regulation system for this isozyme.

Gene targeting of PLC- δ isozymes has been conducted. No single PLC- δ isozyme knockout was fatal. The appearance of PLC- δ 1-deficient mice closely resembled that of nude mice. The isozyme appears to be necessary for commitment of skin stem cells. PLC- δ 3 null mice had no apparent phenotype, but combined deficiency in both PLC- δ 1 and - δ 3 was embryonic lethal. Male PLC- δ 4-deficient mice were infertile. It was postulated that this isozyme is required for the acrosome reaction of sperms.

PLC- ϵ

PLC- ϵ is the biggest PLC (>200 kDa) thus far recognized. It contains a CDC25-like guanine nucleotide exchange factor (GEF) domain in the N terminus, and two copies of Ras-binding motifs (RA domains) following the C2 domain (Figure 2). It has been shown that (1) PLC- ϵ is capable of hydrolyzing PIP2 both *in vitro* and *in vivo*, (2) the CDC25-like domain indeed has a GEF activity and is able to activate Ras and Rap GTPases, and (3) the RA domains bind to active GTP-forms of Ras or Rap. Because of the presence of domain structures that interact with small GTPases of the Ras superfamily, it seems likely that regulation of PLC- ϵ involves this class of proteins. Small GTPases seem likely to function as both regulators (upstream of PLC- ϵ) and effectors (downstream). Studies reported so far are still not sufficient to portray the exact mechanism by which this isozyme functions in the cell.

PLC- ϵ -null mice are viable but show defects in cardiac development and function.

PLC- ζ

A novel type of PLC named PLC- ζ (~70 kDa) was recently identified as a sperm-specific isozyme. PLC- ζ has a very primitive structure. It lacks the N-terminal PH domain (Figure 2)

and rather resembles PLCs found in plants or yeasts. A phylogeny analysis revealed that it is the least divergent from a hypothetical precursor among all mammalian PLCs. It has been shown that this sperm-specific isozyme is responsible for calcium oscillation in fertilizing eggs.

PLC- η

PLC- η s (η 1 and η 2; 115 kDa) are the newest member of the PLC family. PLC- η contains a C-terminal extension with a unique sequence in addition to the common structure. The regulatory mechanism for this new isozyme is mostly unknown, but an activation mechanism via G protein $\beta\gamma$ -subunit has been suggested. Both PLC- η isozymes are highly expressed in neuron-enriched regions of the brain.

Glossary

Brefeldin-A ADP-ribosylated substrate (BARS) Plays a critical role in the fission step of COPI vesicle formation from Golgi.

Coat protein or COPI An ADP ribosylation factor (ARF)-dependent adaptor protein involved in membrane traffic.

NF- κ B (nuclear factor-kappaB) A heterodimeric protein composed of different combinations of members of the Rel family of transcription factors.

Piwi-interacting RNA (piRNA) The largest class of small RNA molecules that is expressed in animal cells.

RNA interference (RNAi) A system within living cells that takes part in controlling which genes are active and how active they are.

Small interfering RNA (siRNA) Sometimes known as short interfering RNA or silencing RNA, is a class of double-stranded RNA molecules, 20–25 nucleotides in length, that play a variety of roles in biology.

SNARE (an acronym derived from “SNAP (Soluble NSF Attachment Protein) REceptor”) proteins These mediate vesicle fusion, that is, the exocytosis of cellular transport vesicles with the cell membrane at the porosome or with a target compartment (such as a lysosome).

Son of Sevenless (Sos) A guanine nucleotide exchange factor (GEF) that activates monomeric GTPases such as Ras and Rac1.

Introduction

Phospholipase D (PLD) enzymes catalyze transphosphatidylation at the phosphodiester bonds found in a select but wide variety of substrates. Transphosphatidylation classically involves exchanging head groups of glycerophospholipids, but the range of substrates acted upon by the extended PLD superfamily is more extensive than just lipids. The most frequent reaction mediated by PLDs is cleavage of a substrate by hydrolysis, but in some cases, use of a nonwater lipid donor combines two lipids to result in synthesis of a new lipid.

The most widely studied PLD activity involves cleavage of the membrane lipid phosphatidylcholine (PC) to yield free choline and phosphatidic acid (PA; [Figure 1](#)). PA is an extensively studied bioactive lipid second messenger that effects changes in many cellular-signaling pathways and functions, depending on the cell type and subcellular location of PA generation. PA uses multiple mechanisms to achieve its effects, including acting as a lipid anchor to recruit proteins to sites of active signaling, functioning as an activator for selected enzymes, serving as substrate to generate other bioactive-signaling lipids, or even facilitating membrane curvature based on its cone-shaped physical structure.

The signaling pathways regulated by PLD and PA connect to many different cell biological processes, and from there to many different physiological processes, the latter of which are much less well defined at present. The cell biological processes include many different types of membrane vesicle trafficking and dynamic organization of the cytoskeleton, the control of cell growth and apoptosis, and interaction of the cell with its environment. These processes affect exocytosis, endocytosis, membrane biogenesis, cell migration, cell adherence, cell survival, and proliferation, which, in turn, affect physiological events such as viral budding from the Golgi complex, survival of

bacteria in the respiratory tract in insects, sporulation in yeast, stress responses in plants, phototransduction in flies, intersegmental vessel formation in zebrafish, and mitochondrial fusion, platelet activation, and neutrophil migration in mice.

PLD Structure

PLD superfamily members are defined by the presence of a consensus sequence, HXK(X)4D(X)6GSXN, known as the HKD domain, which comprises half of the catalytic site. The PLD catalytic core is composed of two HKD motifs that juxtapose to create the active site. Most superfamily members encode two HKD domains, and crystal structures of bacterial family members suggest that PLD proteins assemble as monomers. There are a few members of the superfamily that have only one domain, and accordingly need to dimerize to manifest catalytic activity. Both HKD domains must be intact for PLD to be catalytically active. The His residues mediate the transphosphatidylation reaction.

Prokaryotic PLDs encode just the PLD catalytic domain and function as soluble enzymes. MitoPLD, a mammalian PLD similar in size to prokaryotic PLDs, has, in addition, a leader sequence that targets it to mitochondria. Other superfamily members in yeast, plants, and animals, though, have added many types of domains and motifs to achieve targeted subcellular localization and regulated activity. PC-specific yeast, mammalian, and plant PLDs encode PX (phox) and PH (Pleckstrin homology) domains that function to recruit the PLDs to specific subcellular membranes through selectively binding to certain phospholipids or proteins. Similarly, these PLDs encode a short, basic amino acid-rich motif that binds phosphatidylinositol 4,5 bisphosphate (PI4,5P₂), which regulates both PLD localization and activation. By contrast, most plant

Figure 1 PLD hydrolysis of phosphatidylcholine to generate phosphatidic acid.

PLDs have a conserved C2 domain that enables regulation of the PLDs by calcium binding. Finally, mammalian PLD1 has binding sites for protein kinase C (PKC) and the small guanine triphosphatase (GTPase) families of adenosine diphosphate ribosylation factors (ARF) and Rho proteins, which regulate PLD1 activity through the interactions.

Posttranslational modifications are not essential for PLD activity. Yeast and mammalian PLDs undergo palmitoylation in their PH domain, which similarly is not necessary for enzymatic activity, but instead affects subcellular localization. Mammalian PLD also undergoes ubiquitination, which may control its degradation. The most interesting posttranslational modification is phosphorylation, because PKC is well established as an activator of PLD. However, PKC activates PLD1 via an adenosine triphosphate (ATP)-independent mechanism through interaction of the PKC regulatory domain with the amino terminus of PLD1. In fact, in the presence of ATP, PLD activity is diminished, suggesting that PKC-mediated phosphorylation plays a modest inhibitory role on PLD enzymatic activity. Nonetheless, *in vivo*, phosphorylation by other serine/threonine or tyrosine kinases may promote PLD activity.

Roles for PLDs in Cells and Organisms

Bacterial PLD

Yersinia pestis is a pathogenic bacterium transmitted by flea bite that causes the plague. A number of factors contribute to the virulence of *Y. pestis*, one of which is a PLD family member, Yersinia murine toxin (Ymt). Ymt has two HKD domains and has been shown to catalyze the cleavage of PC, phosphatidylserine, and phosphatidylethanolamine *in vitro*. Ymt as the name implies, is toxic to rats and mice, causing hypotension and vascular collapse when injected as a purified protein, and hypothetically as a result of its release from lysing bacteria during tissue invasion. However, bacteria lacking Ymt are not significantly less toxic to mice, and the Ymt protein is expressed at higher levels by the bacterium at 26 °C than at 37 °C, suggesting that its primary

role might take place in its flea host. In fact, Ymt, through a mechanism not currently well understood, appears necessary for survival of the bacterium in the flea digestive tract.

Many pathogenic bacteria also express Nuc, a highly divergent PLD family member with only one HKD domain that dimerizes to function as an endonuclease. Nuc is exported into the periplasmic space and may be released during bacterial invasion to promote movement of the bacteria through damaged tissues.

Yeast PLD (Spo14)

Yeast PLD selectively hydrolyzes PC to generate PA. Yeast PLD was identified in *Saccharomyces cerevisiae* as being required for sporulation, and hence denoted *spo14*. Extensive studies revealed a requisite role of PLD in the prospore membrane formation step that leads to creation of the spore's plasma membrane and cell wall. More specifically, Golgi-derived secretory membrane vesicles traffic properly to the meiotic plaque, an electron-dense scaffold on the outer surface of the spindle body, but the vesicles then fail to fuse to form the prospore membrane. Mechanistically underlying this failure, the PA produced by *spo14* has been shown to recruit spo20, a t-SNARE (soluble NSF attachment protein receptor (SNARE)) required for the vesicle fusion step, to the site of prospore membrane formation. Spo20 encodes a 40-residue basic amino-acid-rich domain that specifically binds to PA, and use of this domain has been made to create a fluorescent PA sensor that identifies PA in living yeast and mammalian cells. *Spo14* and PA also undertake additional roles during sporulation, but these are less well understood.

PLD activity is not essential during vegetative yeast growth, but becomes required when other components of the secretory machinery, such as Sec14, are absent. Although the exact role is complicated, PLD appears to be a component of a checkpoint mechanism that monitors levels of cellular PC.

Zebrafish

Zebrafish have two PLD genes that closely correspond to the two classic, PC-specific mammalian genes, PLD1 and 2. *pld1* transcripts are present throughout development, and knocking down the *pld1* gene using morpholinos results in an intersegmental vessel-developmental defect.

Drosophila

Drosophila have a single PLD gene that is expressed throughout development and in adulthood. Flies lacking PLD (PLDnull flies) are viable, but less so than PLD heterozygous mutants. A prolonged cellularization phase is observed in PLDnull flies, as well as morphological defects that have not been well specified. Overexpression of PLD during development also results in morphological defects and lethality.

PLD involvement in photoreceptors

Drosophila have compound eyes that are made up of hundreds of photoreceptor cells. Each photoreceptor cell is made up of a cell body and a rhabdomere. Photoreceptor transduction occurs in the rhabdomere which is a specialized compartment

that has polarized vesicle trafficking. Overexpression of *Drosophila* PLD produces PA that disrupts rhabdomere formation.

PA is important in the signal transduction pathway used for photoreceptors. Photoactivation of rhodopsin causes it to change its conformation to become metarhodopsin. Metarhodopsin then activates PLC β , which hydrolyzes PI(4,5)P₂ to generate diacylglycerol (DAG), which, in turn, opens transient receptor potential channels, causing changes in membrane potential and creation of a visual signal. The signal is then terminated by DAG kinase-mediated phosphorylation of the DAG to PA, which is then cycled back to reform PI(4,5)P₂. PLDnull flies have normal-appearing photoreceptors but are 50-fold less sensitive to light, indicating a role for PLD in the phototransduction-cycling process. PLD-generated PA may also play a role in protection of the rhabdomeres under low-light conditions by undergoing dephosphorylation to generate small amounts of DAG.

Plant PLD

PLD was first identified in plants. Up to 12 isoforms of PLD can be found in some plants, such as *Arabidopsis thaliana*. Plant PLDs are divided into subfamilies based on their Ca²⁺ requirement for phospholipid binding, as discussed earlier. Most plant PLDs hydrolyze phosphatidylethanol and phosphatidylglycerol in addition to PC to produce PA.

PLD production of PA in plants is involved in growth, development, and responses to stress. Many of the isoforms have overlapping functions; however, they each seem to have predominant responsibility for a specific stress response. PLD activity increases during periods of nutrient starvation (nitrogen, phosphorus, and potassium) to promote growth and phospholipid hydrolysis. Hyperosmotic stress also induces several PLD isoforms to promote lipid degradation on internal membranes while protecting lipid loss at the plasma membrane. PLD activity may also protect from leaf water loss. PLD can be activated in response to hormones such as ABA, which causes PLD to interact with G α s. Other hormones that stimulate PLD activity include auxin, a developmental hormone, and ethylene, a hormone that promotes senescence. Like mammalian PLD, plant PLD directs localized PA production and can interact with proteins directly. Plant PLD has been shown to interact with actin, microtubules, and cardosina.

Mammalian PLD

Overview

Approximately 30 years ago, it was noted that prolonged exposure of cells to agonists that stimulated PLC to cleave PI4,5P₂ into inositol triphosphate (IP₃) and DAG yielded only brief production of IP₃, but sustained production of DAG. This implied that there was a second pathway through which DAG could be produced, leading to the proposal and discovery of mammalian PLD as an additional source of DAG subsequent to dephosphorylation of newly formed PA. Formation of DAG through this pathway has since been shown to be important in cardiac muscle preischemic conditioning, and in activation of a DAG-responsive RAS exchange factor in T cells.

PLD activity was subsequently noted to increase in many types of cells in response to agonists that stimulated G-protein-

coupled receptors and receptor tyrosine kinases, with the highest levels in secretory cells. Primary alcohols (ethanol and 1-butanol), which competitively suppress PA production by diverting PLD activity to instead make phosphatidylalcohol, were shown to suppress agonist-stimulated secretion. These observations led to a general proposal that PLD is involved in regulated exocytosis. The idea was further supported by the finding the small G-protein ARF, which promotes budding of membrane vesicles from the *trans*-Golgi, is a major activator of PLD.

Cloning of the two classic isoforms of mammalian PLD, PLD1 and PLD2, revealed both overlapping and distinct properties for the enzymes. PLD1 and PLD2 are approximately 50% identical, have the same structure, and similarly hydrolyze PC to generate PA. Most cell types express both isozymes, but the relative expression of each varies between tissues. Both enzymes cycle through a series of subcellular sites. In most cells, PLD1 is found on a diverse collection of perinuclear membrane vesicles, but then translocates to the plasma membrane upon cell stimulation and returns to the perinuclear vesicles by passing through endosomes. PLD1 is observed in many cell types to colocalize with lysosomes, the Golgi and endoplasmic reticulum (ER). In some cells, the majority of PLD1 is found in the steady state on the plasma membrane, but this is more common for PLD2. PLD2 enters the cell via endocytosis upon receptor stimulation, and cycles through endosomes and the Golgi before returning to the plasma membrane. Overexpression or RNA interference (RNAi)-mediated knockdown of PLD1 affects regulated exocytosis in many cell types, whereas overexpression or RNAi-mediated knockdown of PLD2 is more frequently associated with alterations in the actin cytoskeleton and shape of cells. Nonetheless, in some studies, PLD1 has been associated with signaling-induced cell-shape changes and PLD2 has been linked to membrane vesicle trafficking at the Golgi.

Activation

PKC, ARF, and Rho family members synergistically activate PLD1 by binding to individual regions on the protein (Figure 2). PLD2, on the other hand, is constitutively active *in vitro*, and appears to be regulated *in vivo* through repression, which is countered during signaling events. It is not clear how the repression and activation works, but one mechanism

Figure 2 PLD is activated by Rho and ARF GTPases, PKC, and PI4,5P₂ to produce PA from PC.

Figure 3 Cell biological roles for PA.

suggested is that F-actin inhibition of PLD2 may be terminated by binding of ARF to the protein. Alternately, both isoforms require PI4,5P₂ as a coactivator, and it has been suggested that limiting the access of freely available PI4,5P₂ may also serve to regulate the timing and spatial restriction of PLD and/or PLD1 activity.

Function of PA

In mammalian cells, PA has been shown to trigger dynamic relocation of proteins to specific subcellular membrane compartments (Figure 3). For example, PA produced in NIH3T3 cells in response to epidermal growth factor (EGF) stimulation and activation of PLD2 recruits Son of Sevenless (SOS), an exchange factor for the small G-protein oncogene Ras, to the plasma membrane, leading to GTP loading of Ras and cellular transformation. Similarly, in neutrophils, chemokine stimulation leads to PLD activation at the leading edge of the neutrophils, local production of PA, and focused recruitment of DOCK2, an exchange factor for Rac1, which then stimulates F-actin polymerization and polarized cell migration. PA also recruits the Fer and Raf1 kinases, Rac1, and a variety of other proteins to specific subcellular membrane compartments. Finally, PA produced by PLD2 in the Golgi has been reported to recruit brefeldin-A ADP-ribosylated substrate (BARS), a protein that triggers scissioning of Coat protein (COPI) retrograde-transport vesicles.

PA has also been shown to activate proteins, such as PI4P5Kinase, which generates PI4,5P₂, or to serve as substrate for PA phosphatases to generate DAG, or PLA2 enzymes to generate lysoPA, a potent mitogen. Finally, conversion of PC to PA, which has a smaller headgroup, has been proposed to promote negative membrane curvature. Negative curvature is important in membrane vesicle fusion and fission events, lowering the activation energy required to complete the process.

PA regulation of PLD

PA activates PI4P5Kinase which makes PI4,5P₂, and it helps localize ARF and Rho GTPases during actin reorganization. PI4,5P₂ and the GTPases are PLD stimulators, leading in theory to even more production of PA. Conversely, PA also stimulates ARF GAPs, which deactivate ARF GTPases. Multiple such subtle ways to regulate PLD activity are used to exert fine control over PA production.

Tools

In the presence of a primary alcohol such as 1-butanol, PLD will hydrolyze the alcohol preferentially. For this reason, butanol has historically been frequently employed as a means of inhibiting PLD. However, alcohol causes dramatic changes in membrane lipid composition and fluidity that can affect

phospholipid synthesis and receptor-stimulation events. More recently, lipase-inactive PLD alleles have gained popularity as dominant negative inhibitors, and RNAi-mediated knockout of PLD has become routine. Knockout mice and cells have recently been generated and studies on them are beginning to come out.

For short-term studies, small molecule inhibitors for PLD are now available. 5-Fluoro-2-Indolyl des-chlorohalopemide (FIP1), an analog of a pan-PLD inhibitor identified in a screen at Novartis, is a potent inhibitor of PLD1 and PLD2 (IC₅₀ at sub- or low-nM concentrations) that exhibits little cytotoxicity, no off-target effects thus far, and sufficient bioavailability *in vivo* to be usable for animal studies. Isoform-selective analogs have also been developed using combinatorial chemistry, and although somewhat less potent and well studied, offer the option to distinguish between the roles undertaken by the PLD1 and PLD2 isoforms in complex cell settings.

Sensors to detect localized production of PA in cells have also been developed, by fusing PA-binding domains from proteins such as the Raf1 kinase or yeast Spo20 to GFP. Such sensors have been used to image production of PA on macrophage phagosomes and on endocytosing vesicles upon which Ras–Raf1 kinase signaling is taking place.

Cell Biological Processes Regulated by PA

Actin cytoskeleton rearrangement

PLD is involved in dynamic localization of proteins necessary for actin reorganization. Reorganization of the actin cytoskeleton is necessary for many cellular responses such as cell spreading and migration, as well as membrane vesicle trafficking. PA helps localize ARF GTPases and Rho family GTPases. ARF GTPases are GTP-binding proteins involved in vesicle trafficking and actin cytoskeletal rearrangements. Of the six known ARF proteins, ARF1 and ARF6 are highly implicated in PLD-mediated actin rearrangement. ARF1 is associated with Golgi complex formation and is known to be required for coated vesicle formation, whereas ARF6 is associated with endosomal membrane trafficking and actin cytoskeletal rearrangements. Rho GTPases are another group of GTP-binding proteins that can regulate actin polymerization. PLD interactions with Rho family GTPases are independent of ARF interactions, although, in some cases, Rho interactions have been shown to enhance ARF-mediated effects. Rho GTPases are involved in formation of lamellipodia, sheet-like actin structures used to form a leading edge during cell migration, filopodia, which are finger-like projections of the cytoskeleton, and stress fibers used for cell adhesion and lagging edge cell migration. Rho-family GTPase members that are important in PLD-mediated actin rearrangement include Rac1 and Cdc42.

F-actin has been shown to stimulate PLD activity. Concentration of PA at filaments attract and orient ARF6 and Rac1 which direct actin filament formation while stimulating PLD to produce more PA. PLD is also involved in steps prior to GTPase activity. DOCK2, an exchange factor for Rac1, localizes to the leading edge of the plasma membrane in response to PA production, leading to Rac1 activation, F-actin polymerization, and lamellipodia formation. PLD2 activity also regulates myosin activity through recruitment and inhibition of myosin phosphatase, an inhibitor of myosin activity.

Finally, studies on PLD1 knockout mice, which are otherwise viable and overtly normal appearing, have indicated that integrins on platelets lacking PLD1 are activated poorly, leading to decreased clot formation and resulting in protection from pulmonary embolisms and strokes. It is not clear whether the requirement for PLD1 generation of PA is acutely required during thrombus formation, or whether the phenotype reflects long-term PLD1 deficiency.

Vesicle trafficking

Subcellular localization of PLD has indicated that both isozymes are frequently present where the formation of vesicles occurs, such as at the plasma membrane, the Golgi apparatus, and in the endosomal pathway. Generally, PLD is stimulated during vesicle trafficking. PLD-produced PA promotes vesicle formation due to its ability to encourage membrane curvature and to recruit proteins like dynamin and BARs that mediate vesicle scissioning. PA also facilitates SNARE-mediated vesicle fusion. PLD involvement in specific vesicle trafficking events is described below.

Endocytosis

PLD has been proposed to be involved in endosomal recycling; treatment of HeLa cells with 1-butanol results in accumulation of recycling endosomal membrane tubules. Inhibiting the PLD activators PKC and RalA or overexpression of dominant negative PLD1 or PLD2 or PLD RNAi inhibits the internalization of epidermal growth factor receptor (EGFR). PLD2 activity has also been linked to endocytosis of μ -opioid receptors and metabotropic glutamate receptors 1 and 5, whereas PLD1 activity has been associated with B-cell receptor trafficking. Endocytosis of receptors on the plasma membrane can occur through a clathrin-dependent or -independent manner. ARF6 has been shown to associate with the clathrin-independent endosomal pathway and endosomal recycling vesicles. Interestingly, it has recently been demonstrated that PLD1 and 2 bind dynamin in its GTP-bound form and stimulate its GTPase activity, which is required during vesicle scissioning in clathrin-dependent endocytosis.

Exocytosis

Inducers of exocytosis also stimulate PLD at the plasma membrane. Isolated chromaffin cells have been used extensively to study exocytosis and PLD stimulation. Chromaffin cells are neuroendocrine cells found in the adrenal gland. PLD1 appears to be most involved in exocytosis because dominant negatives and small interfering RNA (siRNA) for PLD1, but not PLD2, impair exocytosis. There is evidence that syntaxin, a SNARE membrane associated protein, may provide a polybasic-binding site for PA, allowing PA to concentrate at specific sites. Alternately, PA may help to recruit syntaxin or affect its function. The major interacting partners for PLD1 in exocytosis are ARF6, RalA, Rac1, and RSK2. ARF6 regulates exocytosis in chromaffin and PC12 cells, and PLD1 activation by ARF6 promotes this process. It has been proposed that ARF6 controls the spatiotemporal production of PA to restrict its formation to contact sites between granules and the plasma membrane. SNARE-mediated vesicle fusion is enhanced by the presence of PA on the t-SNARE-containing

membrane surface. PLD1 traffics to the plasma membrane on v-SNARE-containing membrane vesicles, but then binds to and is activated by PI4,5P₂ on the t-SNARE-containing membrane surface, where it then produces PA to recruit v-SNAREs, which have a region of basic amino acids known to be critical for the fusion process. RalA has been shown to interact directly with PLD1 where it can enhance ARF6 stimulation. There are also suggestions that Rac1 is involved in spatiotemporally regulating exocytosis by PLD1. Lastly, RSK2, which is part of the S6 kinase family, has been shown to phosphorylate PLD1, and this phosphorylation is essential to exocytosis in chromaffin cells.

Golgi

Primary alcohols inhibit protein export from the ER to the Golgi and the release of vesicles from the *trans*-Golgi network. The formation of coated vesicles is also inhibited by ethanol. PA dephosphorylation to form DAG, which can activate PKC, has also been shown to regulate vesicle trafficking at the Golgi apparatus.

Signal transduction

In addition to vesicle trafficking, PLD-produced PA serves as a signal transducer that can recruit proteins. The negative charge of PA can attract and orient other proteins for activity during signal transduction events.

Epidermal growth factor receptor

Growth factors have been shown to stimulate PLD activity. The EGF receptor dimerizes upon stimulation by its ligand EGF, resulting in phosphorylation that attracts signal-transducing proteins such as Src and Grb2. PLD is activated by this hub of proteins. EGFR signals are altered by endocytic internalization, which has been shown to be PLD mediated.

Mammalian target of rapamycin

Mitogen signaling activates PLD. Increased PLD activity is associated with cell survival. These effects may be mediated via PA's interactions with mTOR, the mammalian target of rapamycin. mTOR is a kinase that transduces cell survival signals by phosphorylating downstream targets. PA promotes mTOR phosphorylation of S6 kinase and Akt. PA binds to the internal FKBP12 domain of mTOR in a competitive manner with rapamycin. PA likely stabilizes mTOR complexes of mTOR and Raptor, which together form the mTORC1 complex, and mTOR and Rictor, which form mTORC2. It is likely that mTORC1 and mTORC2 have different binding affinities for PA.

PLD and cancer

There is emerging evidence that PLD is upregulated in cancer, which makes PLD a potential therapeutic target. PLD is activated in response to growth factors and participates in mitogen and cell survival signal transduction. PLD1 transcription may be increased in breast cancer in response to nuclear factor- κ B (NF κ B) binding to the PLD promoter region. PLD, often in conjunction with PI3K, is overactive in a number of cancers, and PLD2 driver mutations have been identified in

breast cancer. Ras, which is frequently mutated in cancer to be constitutively active, activates RalA which can then activate PLD. The major mitogen-signaling pathway that ties PLD to cancer involves ERK, AKT, mTOR, and PKC activation. Overactive PLD simultaneously impedes the effectiveness of rapamycin treatment of cancer through increasing mTOR activity. Inhibition of PLD has been shown to inhibit ERK, AKT, and mTOR phosphorylation in lung cancer. PLD activity is associated with vascularization and cell motility.

MitoPLD

A defining property of being included in the PLD family is the attribution of having an HKD motif. A BLAST search identified a protein with a single HKD motif that also contains a mitochondrial-localization signal at its N-terminus. This protein, denoted mitoPLD, is thought to play a role in mitochondrial fusion. MitoPLD is anchored in the outer membrane of the mitochondria and dimerizes to form an active catalytic complex that cleaves cardiolipin to form PA. Overexpression of mitoPLD results in mitochondrial aggregation, while knockdown or dominant negative expression of mitoPLD results in mitochondrial fragmentation. These and other observations indicate that PA produced by mitoPLD at the mitochondrial membrane is involved in mitochondrial fusion. Intriguingly, mice and flies lacking mitoPLD (the *Drosophila* homolog is known as Zucchini) exhibit blocks in germ-cell development during meiosis. Although the mechanism remains unclear, the PA on the mitochondrial surface appears to be required for biogenesis of a specialized form of RNAi (Piwi-interacting RNA (piRNA)) that is also generated at the mitochondrial surface or on juxtaposed structures.

Conclusions

The delineation of roles for PA is undergoing rapid evolution as small molecule inhibitors and mice deficient in the PLD isoforms are being characterized. Inhibition of PLD may prove useful in a variety of disease settings, as will be determined in coming years.

Glossary

Biochemical regulation Process of controlling the activity of enzymes.

Genetic regulation Process of controlling the expression of genes.

Phospholipid A lipid molecule that contains two fatty acyl chains that are esterified to the *sn*-1 and *sn*-2 positions of a glycerol phosphate backbone. Different

phospholipid molecules (e.g., PC, PE) are distinguished by the water-soluble head group (e.g., choline, ethanolamine) that is attached to the phosphate moiety of the molecule.

Saccharomyces cerevisiae A species of yeast that is commonly used in genetic and biochemical research. It serves as an excellent model eukaryotic organism because it is easily cultured and genetically manipulated.

Phospholipids are essential molecules that contribute to the structural definition of the cell. They also play a role as signaling molecules that participate in the regulation of cellular processes. The yeast *Saccharomyces cerevisiae* has been used as a model system to study phospholipid synthesis and its regulation in eukaryotes. Molecular, genetic, and biochemical studies have shown that phospholipid synthesis is regulated in a coordinated fashion. The mechanisms that govern this regulation mediate the messenger RNA (mRNA) and protein levels of the biosynthetic enzymes, as well as their activity and localization.

Phospholipid Composition

The major phospholipids found in the membranes of *S. cerevisiae* include phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylserine (PS) (Figure 1). Mitochondrial membranes also contain phosphatidylglycerol (PG) and cardiolipin (CL). The composition of phospholipids in the cell can vary dramatically when culture conditions are altered. However, the average charge of the membrane phospholipids remains relatively constant. Genetic and biochemical regulation of the enzymes in the phospholipid biosynthetic pathways can compensate for changes in the levels of phospholipids of one charge by orchestrating parallel changes in the levels of phospholipids of the opposite charge.

Phospholipid Synthesis

Phospholipid synthesis is a complex process containing many branch points. A key molecule in this process is phosphatidate (PA). It plays a central role in phospholipid synthesis as the precursor of all phospholipids synthesized via the cytidine diphosphate (CDP)–diacylglycerol (DAG), CDP–choline, and CDP–ethanolamine pathways (Figure 2). In the CDP–DAG pathway, PA is converted to CDP–DAG, which is then utilized for the synthesis of PS, PE, and PC. CDP–DAG is also utilized for the synthesis of PI and CL. In the CDP–choline

and CDP–ethanolamine pathways, DAG is generated from the dephosphorylation of PA, and is utilized for the synthesis of PC or PE when cells are supplemented with choline or ethanolamine, respectively. The DAG derived from PA is also used for the synthesis of triacylglycerols. The nucleotide cytidine triphosphate (CTP) is another important precursor in the synthesis of phospholipids. CTP, which is synthesized from UTP, is the direct precursor of the activated, energy-rich phospholipid pathway intermediates CDP–DAG, CDP–choline, and CDP–ethanolamine (Figure 2).

Synthesis of PA

PA is synthesized from glycerol 3-phosphate via two acylation reactions. The first acylation step, which results in the formation of lysoPA, is catalyzed by the *GAT1*- and *GAT2*-encoded glycerol 3-phosphate acyltransferases. Deletion of either gene does not affect cell viability, but deletion of both genes results in a lethal phenotype. Acylation of lysoPA, which is catalyzed by the *SLC1*-encoded lysoPA acyltransferase, generates PA. In addition to the *de novo* synthesis, PA can be produced from phospholipid turnover: (1) hydrolysis of PC by the *SPO14*/*PLD1*-encoded phospholipase D; (2) phosphorylation of DAG by CTP-dependent DAG kinase (whose structural gene is not yet known); and (3) dephosphorylation of diacylglycerol pyrophosphate (DGPP) by the *DPP1*- and *LPP1*-encoded lipid phosphate phosphatase enzymes.

CDP–DAG Pathway

PS, PE, and PC are synthesized via reactions in the CDP–DAG pathway. The committed step in this pathway is the synthesis of CDP–DAG from PA and CTP. This reaction is catalyzed by the essential enzyme CDP–DAG synthase, which is encoded by the *CDS1* gene. CDP–DAG is then converted to PS by the *PSS1*/*CHO1*-encoded PS synthase. This enzyme displaces the cytidine monophosphate (CMP) moiety of CDP–DAG with serine. PS is then decarboxylated to PE by the *PSD1*- and

Figure 1 Major phospholipids in *S. cerevisiae*. The phospholipid headgroups (i.e., choline, ethanolamine, serine, and inositol) are shown in red.

Figure 2 Pathways for the synthesis of the major phospholipids in *S. cerevisiae*. The pathways shown for synthesis of phospholipids include the relevant steps discussed in the text. The CDP-DAG, CDP-choline, and CDP-ethanolamine pathways are indicated. The enzymes CDP-DAG synthase (CDS), PS synthase (PSS), PS decarboxylase (PSD), and the PE methyltransferases (PMT) catalyze reactions that lead to the formation of PC by the CDP-DAG pathway (shown in blue). Choline kinase (CK), choline-P cytidyltransferase (CCT), and choline phosphotransferase (CPT) catalyze reactions that lead to the formation of PC by the CDP-choline pathway (shown in red). Ethanolamine kinase (ET), ethanolamine-P cytidyltransferase (ECT), and ethanolamine phosphotransferase (EPT) catalyze reactions that lead to the formation of PE by the CDP-ethanolamine pathway (shown in green). The reactions catalyzed by CTP synthetase (CTPS) and phospholipase D (PLD) are shown in brown. A more comprehensive description that includes the synthesis of PA and additional steps in these pathways may be found elsewhere. PA, phosphatidate; CDP-DAG, CDP-diacylglycerol; PS, phosphatidylserine; PE, phosphatidylethanolamine; PME, phosphatidylmonomethylethanolamine; PDE, phosphatidyltrimethylethanolamine; PC, phosphatidylcholine; DAG, diacylglycerol; TAG, triacylglycerol; PGP, phosphatidylglycerophosphate; PG, phosphatidylglycerol; CL, cardiolipin; SL, sphingolipids; PIPs, polyphosphoinositides, DGPP, diacylglycerol pyrophosphate.

PSD2-encoded PS decarboxylases. The *PSD1*-encoded PS decarboxylase is responsible for >90% of the cellular PS decarboxylase activity, while the *PSD2*-encoded enzyme is responsible for ~10% of the enzyme activity. Finally, PE is converted to PC via three sequential methylation reactions. The first methylation reaction is catalyzed by the *PEM1/CHO2*-encoded PE methyltransferase, whereas the last two methylation reactions are catalyzed by the *PEM2/OPI3*-encoded phospholipid methyltransferase.

CDP-Choline and CDP-Ethanolamine (Kennedy) Pathways

When cells are supplemented with choline and ethanolamine, PC and PE are also synthesized via the CDP-choline and CDP-ethanolamine pathways, respectively. In the CDP-choline pathway, choline is phosphorylated with adenosine triphosphate (ATP) to form phosphocholine by the *CKI1*-encoded choline kinase. Phosphocholine is then converted to CDP-choline by the reaction catalyzed by the *CCT1/PCT1*-encoded phosphocholine cytidylyltransferase. In the last step, PC is synthesized from CDP-choline and DAG by the *CPT1*-encoded choline phosphotransferase. The enzyme reactions in the CDP-ethanolamine pathway are similar to those in the CDP-choline pathway. The *EKI1*-encoded ethanolamine kinase catalyzes the phosphorylation of ethanolamine to phosphoethanolamine. Phosphoethanolamine is then converted to CDP-ethanolamine by the *ECT1*-encoded phosphoethanolamine cytidylyltransferase. In the last step, PE is synthesized from CDP-ethanolamine and DAG by the *EPT1*-encoded ethanolamine phosphotransferase. The Kennedy pathways become essential when the enzymes in the CDP-DAG pathway are defective or repressed. Mutants defective in the synthesis of PS, PE, or PC require choline for growth in order to synthesize PC via the CDP-choline pathway. Mutants defective in the synthesis of PS and PE can also synthesize PC if they are supplemented with ethanolamine. Ethanolamine is converted to PE via the CDP-ethanolamine pathway, and the PE is subsequently methylated to form PC via the CDP-DAG pathway. The CDP-choline pathway was once viewed as an auxiliary or salvage pathway used by cells when the CDP-DAG pathway was compromised. However, it is now known that the CDP-choline pathway contributes to PC synthesis even when wild-type cells are grown in the absence of exogenous choline. The PC synthesized via the CDP-DAG pathway is constantly hydrolyzed to form free choline and PA through the reaction catalyzed by the *SPO14/PLD1*-encoded phospholipase D. The free choline is incorporated back into PC via the CDP-choline pathway, and the PA is recycled into PC and other phospholipids via CDP-DAG and DAG.

Other Pathways from CDP-DAG

The essential *PIS1*-encoded PI synthase enzyme catalyzes the displacement of the CMP moiety of CDP-DAG with inositol, resulting in the formation of PI. In this reaction, the water-soluble inositol is provided either by receptor-mediated transport from the growth medium or by *de novo* synthesis from

glucose 6-phosphate. When cells are grown in the absence of inositol, glucose 6-phosphate is converted to inositol 1-phosphate, which is catalyzed by the *INO1*-encoded inositol 1-phosphate synthase. Inositol 1-phosphate is then dephosphorylated to form inositol by the *INM1*-encoded inositol monophosphatase. PI is itself a branch point in phospholipid biosynthesis: it is further converted to multiple phosphorylated forms (polyphosphoinositides) by PI kinases, or its phosphoinositol moiety is transferred to ceramide to form sphingolipids. In the CL pathway, CDP-DAG is converted to phosphatidylglycerolphosphate (PGP) by displacement of CMP from CDP-DAG with glycerol 3-phosphate. This reaction is catalyzed by the *PGS1/PEL1*-encoded PGP synthase. PGP is then converted to PG by PGP phosphatase whose structural gene has not yet been identified. In the last step, CL is synthesized from PG and CDP-DAG by *CLS1/CRD1*-encoded CL synthase.

Regulation of Phospholipid Synthesis

Phospholipid synthesis is regulated by a number of factors. These include water-soluble phospholipid precursors (e.g., inositol and choline), nucleotides (e.g., ATP and CTP), lipids (e.g., PA, CDP-DAG, and sphingolipids), growth phase, and phosphorylation. The regulation of phospholipid synthesis by these factors is complex and mediated not only by genetic mechanisms that control the synthesis of mRNA and protein, but also by biochemical mechanisms that modulate enzyme activity.

Genetic Regulation

The effect of inositol supplementation on phospholipid synthesis is a representative example of genetic regulation. When wild-type cells are grown in the presence of inositol, the levels of PS, PE, and PC decrease, while the level of PI increases. These changes in phospholipid composition result from the coordinated regulation of enzyme activities in phospholipid synthesis. Genetic regulation by inositol supplementation affects the enzyme activities by controlling protein content at the transcriptional level. Thus, inositol supplementation represses the transcription of *INO1* and other genes in the CDP-DAG and CDP-choline pathways, whereas inositol starvation stimulates the transcription of the coregulated genes. In many instances, the repressive effect of inositol is enhanced by the addition of choline or ethanolamine to the growth medium. All of the coordinately regulated genes contain a *cis*-acting element, inositol-sensitive upstream activation sequence (UAS_{INO}), in the promoter region. The UAS_{INO} element has the core consensus-binding site (CANNTG) for basic helix-loop-helix (bHLH) proteins. Ino2p and Ino4p are members of the bHLH family of DNA-binding proteins. They bind the UAS_{INO} element as a heterodimer and activate transcription. In addition, Ino2p (but not Ino4p) contains a transcriptional activation domain and is subject to autoregulatory control. Thus, levels of Ino2p appear to be limiting for the formation of the Ino2p/Ino4p heterodimer. By contrast, Opi1p represses the transcription of UAS_{INO}-containing genes. Opi1p contains a leucine

zipper and two glutamine-rich domains that are required for Opi1p repressor activity. Opi1p mediates its negative regulatory activity through the UAS_{INO} element, but not by direct interaction. Instead, *in vitro* data indicate that Opi1p interacts with DNA-bound Ino2p within the leucine zipper domain of Opi1p. In addition, the global repressor Sin3p interacts with the N-terminal region of Opi1p. Studies using mutant alleles of *INO2*, *INO4*, *OPI1*, and *SIN3* support a model whereby these interactions play a role in the expression of UAS_{INO}-containing genes *in vivo*.

In addition to inositol, the transcription of the UAS_{INO}-containing genes is also regulated by growth phase. Cells entering stationary phase reveal the repression of the *INO1* gene expression even in the absence of inositol from the growth media. The stationary phase repression of *INO1* transcription is also controlled by Opi1p. Deletion of the *OPI1* gene results in the derepression of *INO1* transcription in stationary phase.

Some enzymes in phospholipid synthesis are regulated in an opposite fashion: they are upregulated by inositol and derepressed in stationary phase. For example, inositol supplementation results in an increase in the level of DGPP phosphatase (encoded by *DPP1*) activity in both exponential and stationary phase cells. The activity is greater in stationary phase cells when compared with exponential phase cells, and the inositol- and growth phase-dependent regulation of DGPP phosphatase are additive. Analyses of DGPP phosphatase mRNA and protein levels indicate that transcriptional regulation is responsible for the control of the enzyme activity. This regulation is not mediated through a UAS_{INO} element, as the element does not exist in the *DPP1* promoter.

Biochemical Regulation

Alterations in phospholipid synthesis in response to environmental changes are also regulated by biochemical mechanisms. In addition to its role in regulating enzyme expression, inositol regulates the activity of phospholipid biosynthetic enzymes. Inositol inhibits PS synthase activity as a noncompetitive inhibitor, and regulates PI synthase activity through substrate availability. Since both enzymes share the common substrate CDP-DAG, inositol-mediated regulation of PS synthase activity contributes to the synthesis of PI at the expense of PS.

Phosphorylation is a mechanism by which an enzyme activity may be regulated, and indeed several phospholipid biosynthetic enzymes are phosphorylated. For example, the CTP synthetase, choline kinase, and PA phosphatase enzymes are phosphorylated and activated by protein kinase A, whereas the phosphorylation of PS synthase by protein kinase A results in the inhibition of activity. These phosphorylation reactions favor the synthesis of PC via the CDP-choline pathway.

Lipids regulate some phospholipid biosynthetic enzymes. For example, PS synthase activity is stimulated by PA and

inhibited by CL and DAG. The PA phosphatase enzyme is stimulated by CL, CDP-DAG, PI, and DGPP. PS synthase and PA phosphatase are also inhibited by the sphingoid bases phytosphingosine and sphinganine.

Nucleotides regulate the activity of some phospholipid biosynthetic enzymes. For example, choline kinase is subject to allosteric regulation by its substrate ATP and its product adenosine diphosphate (ADP). ATP promotes the oligomerization of choline kinase, whereas ADP inhibits its activity by affecting the catalytic properties of the enzyme and the apparent affinity of the enzyme for substrates ATP and choline. CTP inhibits PS synthase activity by chelating its cofactor manganese ions. CTP synthetase is regulated by CTP product inhibition. The CTP-mediated inhibition of CTP synthetase activity increases the positive cooperativity of the enzyme for UTP. CTP synthetase with a mutation at Glu¹⁶¹ is less sensitive to CTP product inhibition, and cells carrying the mutant CTP synthetase accumulate elevated levels of CTP. Because CTP inhibits PS synthase activity, the higher levels of CTP result in an increase in the utilization of the CDP-choline pathway at the expense of the CDP-DAG pathway.

In this article, we have only scratched the surface in discussing the complex mechanisms that govern the synthesis of membrane phospholipids. Moreover, once phospholipids are synthesized, they must be transported to the various organelles in the cell. These processes are complex, and in some cases, they regulate phospholipid synthesis. The availability of sequence information of the yeast genome continues to facilitate studies on the molecular, genetic, and biochemical mechanisms that regulate phospholipid synthesis.

Photoinhibition and Photoprotection in Plants, Algae, and Cyanobacteria

Glossary

Light harvesting complexes (LHCs) LHCs are proteins belonging to a multigenic family found in almost all photosynthetic eukaryotes. They bind several pigment molecules and are associated to both photosystems I and II. They are responsible for increasing light harvesting efficiency but members of the multigenic family are also involved in photoprotection.

Nonphotochemical quenching (NPQ) When exposed to intense illumination, photosynthetic organisms activate a mechanism for thermal dissipation of energy absorbed in excess. This response is called nonphotochemical quenching, although the term 'feedback de-excitation' has also been proposed. The nomenclature originates from the fact that NPQ is generally measured by monitoring *in vivo* fluorescence and its activation is detected indirectly by a quenching of emitted fluorescence.

Photoinhibition When exposed to intense illumination, photosynthetic organisms experience oxidative stress due to absorption of excess excitation energy. The oxidative species generated react with proteins and pigments of the photosynthetic apparatus. Photoinhibition is defined as the decrease in photochemical efficiency experienced in response to intense illumination due to radiation damages. Photosystem II is the major target of this phenomenon.

Photoprotection When exposed to intense illumination, photosynthetic organisms may experience oxidative stress due to excess excitation energy absorbed. Photosynthetic organisms are able to activate several distinct regulatory

mechanisms to avoid damages from excess illumination. This kind of response is generally defined as photoprotection.

Photosystem I Photosystem I is a multisubunit complex. It exploits light energy to catalyze the electron transport from plastocyanin to ferredoxin. By working in series with photosystem II, it is responsible of light-driven electron transport from water to the final acceptor NADP^+ .

Photosystem II Photosystem II is a multisubunit complex binding multiple pigment molecules, both chlorophylls and carotenoids. Photosystem II exploits light energy to catalyze the most fundamental reaction in the biosphere, the oxidation of water to molecular oxygen and reducing equivalents.

Protein D1 D1 protein is a central subunit of photosystem II. It binds most of the cofactors fundamental for electron transfer within photosystem II. Under illumination, it experiences a very high turnover rate and is central in the repairing cycle of photosystem II.

Xanthophylls and xanthophyll cycle Xanthophylls are oxygenated carotenoid which are commonly present in photosynthetic apparatus of most photosynthetic organisms. Carotenoids provide photosynthetic organisms with constitutive protection from oxygen reactive species and oxidative stress. However in many organisms, the carotenoid composition changes upon intense illumination. Most commonly, in strong light the xanthophyll violaxanthin is reversibly converted into zeaxanthin. Accumulated zeaxanthin is active in photoprotection.

Light Energy Transduction

Solar radiation is the primary source of energy for the biosphere, and oxygenic photosynthesis is the process by means of which light is converted into the chemical energy that living organisms exploit for their needs. When a photon of visible light is absorbed by the pigments of a light-harvesting component of the photosynthetic apparatus, its energy is converted into electronic excitation which can be transmitted to nearby pigments of the antenna moiety, until it is trapped by the special chlorophyll *a* contained in the reaction centers. Here, electronic excitation is converted into charge separation, one electron being transferred from the excited *chl a* (*chl a*^{*}) to a nearby acceptor molecule. This process takes only a few picoseconds, as it has to compete with the thermal relaxation of molecular excitation. Light, like most forms of energy, can be dangerous when supplied in large amounts.

Oxygen, the By-Product of Photosynthesis, Can Be Harmful

In the photosynthetic apparatus, light absorption in the antenna moiety and charge separation in the reaction centers take place in the presence of molecular oxygen, which is a byproduct of the electron transport activity of photosystem II (PSII), and this creates a potential risk of oxidative stress. Electron transfer reactions in the presence of dioxygen can give rise to the production of highly reactive activated oxygen forms such as singlet oxygen ($^1\text{O}_2$), superoxide ($\text{O}_2^{\bullet-}$), and hydroxyl radical ($\text{OH}^\bullet$).

In particular, the very reactive $^1\text{O}_2$ can easily be created by light in the presence of a photosensitizer such as chlorophyll, which is the main pigment of the photosynthetic apparatus:

Chlorophyll is very efficient in absorbing visible light, and its excited state Chl^* has a lifetime of a few nanoseconds, long enough to allow excitation transfer within the light-harvesting complex and charge separation in the reaction centers. However, if the excitation energy is not used promptly, a spin transition may take place by intersystem crossing to the lower energy state ^3Chl (reaction [1]). The chlorophyll triplet state, with its much longer lifetime (in the microsecond time range), has plenty of time to react with the ground state of molecular oxygen and to produce its activation to singlet state (reaction [2]). $^1\text{O}_2$ is a highly oxidative agent which can react with the pigments, lipids, and proteins of the photosynthetic apparatus, causing oxidative damage and loss of their function.

Therefore, light is both indispensable to and dangerous to photosynthesis. Photosystem II is continually damaged during photosynthetic electron transport, and the extent of damage increases with light intensity. The main damaging agent is $^1\text{O}_2$, produced at the PSII reaction center, and the mechanism for its production is charge recombination. When the $\text{Chl } a$ at the reaction center (P_{680}) is excited, an electron is transferred to the first acceptor pheophytin (Phe), leading to a charge separated state:

In the physiological electron transfer chain, the charge-separated state is stabilized by secondary electron transfer reaction to the first stable quinone acceptor (Q_A) in 200–400 ns [4]. Quinone Q_A is firmly bound to the D_2 protein of the reaction center and acts as a one-electron acceptor. In the subsequent 300–500 μs , the electron is taken up by the two-electron acceptor Q_B , loosely bound to the D_1 protein of the D_1/D_2 heterodimer of the PSII reaction center [5]. When Q_B becomes doubly reduced by a second electron transfer reaction, driven by a second absorbed photon, two protons are taken up from the stromal solution, and the resulting quinole (QH_2) leaves its

binding site on the D_1 protein for the lipidic phase of the thylakoid membrane (Figure 1):

Meanwhile, the charge separation is further stabilized by an electron transfer from the donor side of PSII, that is, Tyr_Z (Y_Z) of the D_1 protein:

Reaction [3], radical pair formation, is an endo-ergonic reaction driven by photon energy, whereas all other electron transfer reactions are downstream, toward increasing redox potentials. Nevertheless, all of them are reversible, and each reaction may proceed backward with a certain degree of probability. In particular, in reaction [3], the charge-separated state may recombine through different pathways. One is an activated pathway:

where charge recombination leads to the excited state of P_{680} , which may eventually relax to ground state by fluorescence emission (retarded fluorescence) or thermal dissipation. Another possibility is direct recombination to ground state:

Both these reactions lead to dissipation of absorbed light energy, thereby decreasing the photosynthetic yield, but they neither activate molecular oxygen nor constitute any threat to the photosynthetic apparatus. However, reaction [9] may also take an alternative route: if the charge-separated state $\text{P}_{680}^+ + \text{Phe}^-$,

Figure 1 Arrangement of redox cofactors according to PSII structure. Electron transport routes are indicated.

which is normally in its singlet state $^1[P_{680}^+ + \text{Phe}^-]$, is given enough time, it may re-phase its spin state to the lower-lying triplet state $^3[P_{680}^+ + \text{Phe}^-]$ by intercrossing system. This charge-separated state may recombine to the triplet state of P_{680} :

As described above, the triplet state of a chlorophyll molecule can easily activate molecular oxygen to its singlet state:

Unlike the situation of the chlorophyll molecules, which act as absorbing pigments in the light-harvesting apparatus, the triplet state of which is efficiently scavenged by carotenoids, in the special case of the P_{680} chlorophyll of the PSII reaction center, there is no protection from carotenoids, as those located at the reaction center are too far away from P_{680} to be efficient scavengers of its triplet state (Figure 1).

Routes [9] and [10] of charge recombination have approximately the same probability of occurring, and charge recombination at the PSII reaction center therefore involves the production of singlet oxygen with a quite high degree of probability.

Photosynthetic organisms exploit solar radiation to support their metabolism. If illumination is low, as in deep water or under dense leaf canopies, light is a limiting factor for growth, and photosynthetic organisms have evolved a system of light-harvesting complexes (LHCs) which increases the capacity for efficient harvesting of light energy. These antenna systems are composed of pigment-protein complexes which absorb light energy and transfer the excitation to reaction centers, where photochemical reactions occur. Antenna systems vary in different groups of photosynthetic organisms, adapting to the environmental conditions encountered. In cyanobacteria,

they are soluble proteins called phycobilisomes, and bind phycoerythrin and phycobillin as pigments. In plants and eukaryotic algae, antenna proteins are all membrane-embedded proteins belonging to the multigenic Lhc family and bind Chl and carotenoids (Figure 2).

Solar radiation in a natural environment is not constant, and while in some conditions it may be limiting, in others, as at midday in full sunlight, it may saturate photosynthetic capacity. Light harvested in excess causes an increase of the excited states in the antenna pigments. This excess excitation is dangerous for the cells, because it may lead to the formation of reactive oxygen species and eventually photoinhibition. Plants, algae, and cyanobacteria have all evolved the capacity for efficiently repairing radiation damage and recovering from photoinhibition. However, they have also evolved mechanisms to dissipate excessive energy safely and to reduce damage to the photosynthetic apparatus by any reactive oxygen species. All these responses go under the name of photoprotection.

Photoinhibitory Damage to PSII

Most authors agree that singlet oxygen production at the PSII reaction center is the main mechanism of photoinhibition, which may be defined as the loss of photosynthetic activity undergone by oxygenic photosynthetic organisms (plants, algae, and cyanobacteria) when light energy is absorbed at a rate exceeding the overall rate of electron transfer through the photosynthetic electron transfer chain.

In these conditions, the quinone pool in the photosynthetic membrane and the quinone acceptors of PSII become fully reduced. At high irradiance, primary acceptor Q_A is stable in its reduced form Q_A^- , and a charge-separated state, formed by photon absorption, can only recombine, as the probability of double Q_A reduction is very low, even at very high irradiance. Thus, with increasing light intensity, singlet oxygen production at the PSII reaction center also increases, causing oxidative damage and loss of photosynthetic activity.

The D_1 Protein of the PSII Reaction Center is Selectively Degraded

It has long been known that the D_1 protein of the PSII reaction center has a very high turnover compared with other chloroplast proteins, and that its turnover rate increases with light intensity. This has been interpreted as evidence that the D_1 protein is the main target of light-induced photooxidation. According to the most popular model, the damaged D_1 protein is recognized by a set of specific proteases which cut it to pieces. A complex repair cycle, involving new synthesis of D_1 and its insertion into the PSII complex, brings the damaged PSII unit back to renewed full activity.

The D_1 Protein as a Sacrificial 'Fuse' System

A different interpretation has also been proposed: degradation of the D_1 protein is not due to the fact that it is preferentially damaged by the oxidative action of singlet oxygen. There is no

Figure 2 Sketch of antenna complexes in various photosynthetic organisms. (a) Cyanobacteria antenna is composed of soluble pigment-binding complexes, called phycobilisomes, which are associated with both PSI and II. (b) In plants and algae, the antenna system is composed of membrane proteins belonging to the LHC multigenic family. In plants and green algae, distinct subunits, LHCI and LHCII, are specifically associated with PSI and II. In other groups of algae, some antenna proteins may be associated with both photosystems.

explanation, based on experimental evidence, why singlet oxygen should preferentially damage the D₁ protein and not other nearby proteins, for example, D₂, which is symmetrically located with respect to P₆₈₀, should also be damaged to same extent. Nor is there any explanation on how proteases would be activated to recognize and degrade the damaged protein. Thus, protease degradation of D₁ may be a protective mechanism, activated by some suitable signal such as the reduction level of the chloroplast or increased concentration of singlet oxygen. Degradation of D₁, disrupting the integrity of the reaction center, would stop the production of singlet oxygen, thus protecting the remaining components of the PSII complex from irreversible destruction.

Charge Recombination to Ground State as a Protecting Mechanism

The yield of charge recombination, with the formation of ³P₆₈₀ and ¹O₂, is modulated by a change in the midpotential of redox couple Q_A/Q_A⁻. This is because the efficiency of the ¹O₂ producing pathway depends on competition between the formation of the triplet state of the radical pair ³[P₆₈₀⁺ + Phe⁻], forward electron transfer (reaction [4]), and direct recombination of the charge-separated states ¹[P₆₈₀⁺ + Phe⁻] and [P₆₈₀⁺ + Q_A⁻] to form the ground state of P₆₈₀. These processes, which do not lead to production of singlet oxygen, depend on the redox potential of Q_A and on the free energy gap between Phe⁻ and Q_A⁻.

In some conditions, which may be of physiological significance, such as high light flux, conformational adjustments of reaction center proteins – induced, for instance, by acidification of the thylakoid lumen – the midpoint potential of Q_A may increase by several dozen millivolts, hindering forward electron transfer from Q_A to Q_B and favoring direct charge recombination to the ground state of P₆₈₀. It has been experimentally shown, in *in vitro* experiments, that the extent of photodamage suffered by PSII depends on the midpoint potential of Q_A/Q_A⁻.

The Mechanism of Photoinhibition of PSII is Still Controversial

Although the molecular mechanisms for PSII photoinhibition have been studied intensively for decades, there is still significant controversy in the literature as regards the primary source of photodamage to PSII. The main controversy is between authors who support the model based essentially on singlet oxygen forming in the various events of charge recombination and those who assign photodamage to the visible light absorbed by the manganese cluster of the oxygen-evolving complex (OEC) on the donor side of PSII.

In the latter case, it is proposed that the primary event in photodamage to PSII by both UV-B and visible light is due to the photosensitizing action of the Mn cluster. This is based on the similarity of the action spectrum for impairment of the water splitting activity, as monitored by light-induced electron transport from H₂O to dichlorophenolindophenol (DCPIP) in the presence of an intact preparation of thylakoid membranes,

with the absorption spectrum of a dimeric Mn(III/IV) model compound. According to this model, the first harmful action of a high photon flux is impairment of OEC activity, which leaves primary donor P₆₈₀ permanently in its oxidized form P₆₈₀⁺. This type of phenomenon, called 'donor-site photodamage', had already been observed in the case of photoinhibition induced by UV-B light. In such conditions, the light absorbed by chlorophylls starts exerting its harmful action on the electron transfer chain, but degradation of the D1 protein is not due to the formation of singlet oxygen, which is instead involved in impairment of the repair cycle.

Photosystem I Light Damage

PSI is also a potential source of radical species under high light. However, PSI normally undergoes far less light-induced damage than PSII. First of all, charge recombination at the PSI reaction center, with dissipation of energy as heat, is an efficient process here and thus provides an efficient protection mechanism when light is in excess.

Nevertheless on the PSI acceptor side, reduced ferredoxin or Fe-S clusters can be directly oxidized by O₂, leading to the production of O₂^{•-}. This superoxide radical species is rapidly converted into H₂O₂ by superoxide dismutase (SOD). Efficient dismutation of superoxide is critical to protect PSI from photodamage, and *Arabidopsis* mutants in which SOD activity was impaired do show pronounced photosensitivity.

H₂O₂ produced by SOD may be converted into O₂ and H₂O by catalase, which is found in plant peroxisomes but not in chloroplasts. In these organelles, H₂O₂ produced by SOD is rapidly consumed by ascorbate peroxidase, which synthesizes a mono-dehydroascorbate radical (MDA). MDA is extremely reactive and can be reduced by MDA reductase by photosynthetic electrons originating from PSI. Altogether, these reactions are called the water–water cycle, because electrons generated from water oxidation at PS II are used to reduce O₂ back to water at PSI. The water–water cycle eliminates excess electrons and thus plays a photoprotective role, as has been shown in mutants lacking ascorbate peroxidase, which have increased photosensitivity. However, this cycle also contributes to the generation of a ΔpH and thus contributes to balancing the ratio between reducing power and ATP.

As a further protection mechanism, photodamage to PSI has been shown to affect first the antenna complexes, while photochemical activity is preserved. Thus, the PSI protection strategy is quite different from that of PSII: in the former, light damage first affects the light-harvesting antenna, which acts as a screen against harmful agents, leaving the reaction center intact and still capable of performing charge separation. In contrast, the PSII reaction center is damaged first, but is then efficiently and continually restored by the so-called 'repair cycle'.

Dissipation of Excess Singlet States: Nonphotochemical Quenching

The PSII reaction center is continually subjected to oxidative stress and, besides its own protection strategy, can continually repair itself. However, self-repairing is a complex, energetically expensive process. An additional strategy has therefore evolved

in oxygenic organisms, consisting of dissipating excess energy absorbed by the antenna (LHCII) before it is transferred to the reaction center. Reducing the concentration of excited states in the LHCII decreases the probability of generating reactive oxygen species at the reaction center.

An increase in light flux rapidly activates thermal dissipation of chlorophyll excitation, in a process called nonphotochemical quenching (NPQ). This capacity is particularly important in plants, to reduce light damage during the rapid changes in illumination which are common in natural environments. The mechanism is active at the LHC of PSII and involves a light-induced decrease in PSII fluorescence yield (quenching).

When light harvesting exceeds the capacity for light utilization in assimilatory reactions, an accumulation of protons in the thylakoid lumen, associated with electron transport in the photosynthetic chain, causes a rapid decrease in pH which triggers NPQ. This mechanism relies essentially on protein conformational changes, does not require changes in gene expression, and can be activated within seconds of the increase in illumination. The capacity for activating NPQ has been identified in several organisms such as plants, algae, and cyanobacteria, although with great differences in the molecular mechanisms and proteins involved. The differences are due to the fact that the antenna systems are different in these organisms and therefore so are their regulatory mechanisms. As already mentioned, the antenna systems of plants and eukaryotic algae are composed of membrane-embedded proteins belonging to the LHC multigenic family, whereas in cyanobacteria, soluble pigment-binding proteins, called phycobilisomes, are associated with the reaction centers (Figure 2).

Most of the available information comes from plants, in which NPQ activation is known to depend on the LHC-like protein PSBS. Several pieces of evidence support the hypothesis that PSBS does not quench the Chl singlet excited states by itself, but works as a sensor of luminal pH, which turns on NPQ in neighboring antenna proteins, where the quenching of $^1\text{Chl}^*$ actually occurs. This is possible because, under strong illumination, low luminal pH induces protonation of two glutamate residues of PSBS, thereby inducing a conformational change in the antenna proteins which in turn increase the rate of thermal dissipation of chlorophyll excited single states. Full activation of NPQ is also suggested to involve protein re-organization within the thylakoid membrane.

Whereas NPQ in plants is recognized to involve PSBS and antenna proteins, the pigment molecules involved and the precise mechanism of energy dissipation are still debated. Fluorescence quenching has been proposed to depend on direct energy transfer from chlorophylls to carotenoids. This transfer may be possible in antenna complexes after a conformational change occurring in the NPQ condition. An alternative hypothesis suggests that quenching occurs via a charge transfer within a chlorophyll–carotenoid dimer. In this case, during NPQ, a $[\text{Chl}^{\bullet-} \text{carotenoid}^{\bullet+}]$ radical pair state is first generated and then quickly recombines to the ground state, thereby dissipating excitation energy as heat.

Nonphotochemical Quenching in Algae

Although less information is available, most species of algae can also activate NPQ. Their antenna systems are also

composed of members of the LHC multigenic family, although different algal groups have different specific composition. Interestingly, PSBS protein has never been detected in algae so far, thus raising the question as to how NPQ is activated in them. In one green alga, *Chlamydomonas reinhardtii*, another protein, LHCSR, has been identified as responsible of NPQ. LHCSR also belongs to the LHC family, but does not show any similarity with PSBS. LHCSR is widespread among algae and, although molecular evidence is still missing, LHCSR is probably responsible for NPQ activation in many algal groups.

Instead, LHCSR is not found in vascular plants, and some mosses are the only known land organisms retaining this protein. Mosses also have PSBS like all other land plants, suggesting that, during land colonization, photosynthetic organisms lost the LHCSR-dependent NPQ typical of algae after acquiring that dependent on PSBS typical of plants.

It is still not clear whether LHCSR works as a modulator of other antenna proteins, like PSBS, or whether it is a direct quencher of excitation energy. The second hypothesis may be the correct one since, unlike PSBS, LHCSR directly coordinates chlorophylls and carotenoids and may, in principle, act as a quencher of excitation energy.

Nonphotochemical Quenching in Cyanobacteria

A response called NPQ has also been described in cyanobacteria, although its presence was long debated in the past. As already mentioned, light-harvesting apparatus in cyanobacteria is completely different than that in plants and algae, and NPQ does have very different features. In cyanobacteria, NPQ is specifically activated by blue light and not by all visible light, as in plants and algae. However, in both cyanobacteria and plants, NPQ consists of the quenching of antenna fluorescence emission, and antenna complexes (in this case, phycobilisomes) have been shown to be necessary for NPQ activation. NPQ in cyanobacteria also requires the presence of orange carotenoid protein (OCP) which induces quenching by interacting with phycobilisomes in a still unclarified mechanism. OCP is a soluble protein which coordinates a carotenoid molecule found only in cyanobacteria. It appears to act as both photoreceptor and mediator of a photoprotective energy dissipation mechanism, which decreases the amount of energy reaching both photosystems from the phycobilisomes.

Xanthophyll Cycle

Low luminal pH is a key signal of excessive illumination and is very important in regulating photosynthesis. In plants and algae, in addition to NPQ, on a minute timescale, it also activates the conversion of the carotenoid violaxanthin into zeaxanthin. This reaction is catalyzed by a luminal enzyme, violaxanthin de-epoxidase (VDE), a member of the lipocalin family of proteins. VDE is activated at low pH, which induces a conformational change and a change in its location, with its association with the thylakoid membranes where the substrate violaxanthin is found.

The presence of zeaxanthin modulates the photosynthetic apparatus and increases photoprotection at various levels. It strongly enhances NPQ, and zeaxanthin-binding antenna complexes are more efficient in dissipating excess energy as

Figure 3 Sketch of xanthophyll cycle. Under strong illumination, xanthophyll violaxanthin is converted into zeaxanthin by luminal enzyme violaxanthin de-epoxidase (VDE). VDE is activated by decrease in lumenal pH resulting from strong illumination; it dimerizes and associates with membrane, where substrate is found. In low or no light, zeaxanthin is converted back to violaxanthin by stromal enzyme zeaxanthin epoxidase.

heat. However, zeaxanthin is also particularly efficient as a scavenger of reactive oxygen species, since it may dissipate any singlet oxygen which may form.

When light goes back to normal intensities, zeaxanthin is converted back to violaxanthin by zeaxanthin epoxidase, closing the so-called xanthophyll cycle (Figure 3).

Glossary

Circadian photoentrainment The shifting of the (endogenous) circadian clock by light so that it is synchronized with the ambient light–dark cycle.

Depolarization Phenomenon in which the electrical potential inside the cell relative to outside becomes more positive compared to the resting state.

Hyperpolarization The electrical potential inside the cell relative to outside becomes more negative compared to the resting state.

Nonselective-cation channel An ion channel that allows only cations (largely Na^+ , K^+ , and Ca^{2+}) to go through but does not discriminate much between them.

Phototransduction The cellular mechanism that transduces light into an electrical signal in the photoreceptor.

Photoreceptors are cells that can detect light by virtue of a light-absorbing pigment they contain. In most cases, photoreceptors are neurons in the nervous system, and they signal light to the organism for behavioral changes. In some cases, however, photoreceptors are simply modified epithelial cells, such as melanophores in lower animals that can change color by virtue of aggregation or dispersion of intracellular pigmented granules in response to illumination. In humans, all photoreceptors known to date are present in the retina of the eyes. In lower vertebrates such as birds and fish, photoreceptors are also present in the pineal gland and elsewhere in the brain (deep-brain photoreceptors). In some lizards and frogs, photoreceptors are present in the parietal eye (also called the third eye or the frontal organ). In invertebrates, photoreceptors are present in diverse locations either singly or in small or large clusters to form well- or ill-defined eyes. In this article, the discussion is confined to vertebrate photoreceptors in the nervous system.

Retinal Photoreceptors

The well-known retinal photoreceptors in all vertebrates are the rods and cones. Rods are extremely sensitive to light, being able to detect and signal the absorption of a single photon; they are responsible for dim-light vision. Cones are much less sensitive to light, and they also adapt to steady light much more effectively than rods; they are responsible for bright-light vision. In most animals, including humans, rods are predominant in the retina. In occasional diurnal species (such as ground squirrel), however, cones are very abundant.

Rods

In mammals, all rods in a retina are identical. Morphologically, they can be distinguished into the outer segment, the inner segment, the cell body, and the synaptic terminal (Figure 1).

Outer Segment

The outer segment is a modified cilium that has become a highly expanded structure, with hundreds of internalized

membrane disks stacked on top of each other and oriented transverse to the longitudinal axis of the cell. The membrane disks are chock-full of the rod visual pigment, rhodopsin, a transmembrane protein. Rhodopsin consists of rod opsin, the apoprotein, covalently linked to the chromophore, 11-*cis*-retinaldehyde (a derivative of vitamin A). In the mammalian retina, there is a single class of rods, all with the same opsin. The wavelength of maximum absorption (λ_{max}) of rhodopsin is near 500 nm (blue-green monochromatic light).

Inner Segment

The inner segment contains much of the metabolic machinery of the cell, and gives rise to the outer segment. The part of the inner segment adjacent to the outer segment is packed with mitochondria, reflecting the heavy metabolic load on the cell.

Cell Body

The cell body contains primarily the nucleus of the cell.

Synaptic Terminal

The synaptic terminal contacts second-order retinal neurons, including the bipolar and horizontal cells. It releases glutamate as the neurotransmitter. The synapse has a ribbon structure that is typical of most sensory neurons.

Cones

In humans, there are three types of cones, each with a different cone opsin covalently linked to 11-*cis*-retinaldehyde. The three cone pigments have λ_{max} at ~430 nm (blue), 530 nm (green), and 560 nm (yellow), respectively. The functional interactions between the three cone types allow us to perceive colors. The morphology of cones is very similar to that of rods, except that the membrane disks in the outer segment are continuous with the plasma membrane.

Figure 1 Diagram to show the overall morphology of a retinal rod photoreceptor and its response to light. See **Figure 2** for the phototransduction mechanism underlying the response. Reproduced from Yau K-W (1994) Phototransduction mechanism in retinal rods and cones. *The Friedenwald lecture. Investigative Ophthalmology and Visual Science* 35: 10–32.

Phototransduction

The process by which light triggers an electrical response (the signal that neurons use to communicate with each other) in rods and cones is called phototransduction. It is similar in both photoreceptor classes, and is now very well understood (**Figure 2**). There are nonselective cation channels on the plasma membrane of the outer segment that open (i.e., conduct ions) upon binding intracellular cyclic guanosine monophosphate (cGMP) (cGMP-gated channels). In darkness, the free cGMP concentration in the outer segment is relatively high, thus keeping some of these cGMP-gated channels open. These open channels depolarize the cell and sustain a continuous release of glutamate from the synaptic terminal. Upon absorbing a photon, the 11-*cis*-retinaldehyde in a visual pigment molecule isomerizes to all-*trans*-retinaldehyde, as a result of which the opsin moiety undergoes several extremely rapid conformational changes, one of which (meta-II state) is catalytically active. It activates a G protein called transducin, which, in turn, stimulates a cGMP-phosphodiesterase to hydrolyze cGMP. As a result, the free cGMP concentration decreases, and the cGMP-gated channels close, producing a membrane hyperpolarization that reduces or completely stops neurotransmitter release from the synapse. This signal is picked up by the second-order retinal neurons. The inward, depolarizing membrane current through the open cGMP-gated channels in darkness, in part, involves Ca^{2+} (the rest is mostly Na^{+}), which is steadily pumped out of the cell by an antiporter involving exchange of external Na^{+} for internal Ca^{2+} and K^{+} . The dark Ca^{2+} influx decreases or stops in the light because

Figure 2 Phototransduction mechanism underlying the light response in rods. GCAP, guanylate-cyclase-activating protein; $h\nu$, photon; Rh, rhodopsin; Rh^* , photoactivated rhodopsin; $\text{Rh}^*\sim\text{P}$, phosphorylated form of rhodopsin; RGS-9, regulator of G-protein-signaling isoform 9; PDE_γ , inhibitory (γ) subunit of the phosphodiesterase; +, stimulation or positive modulation; –, inhibition or negative modulation. RGS-9, together with its associated proteins R9AP (RGS-9-anchoring protein) and $\text{G}_{\beta 5}$ (a previously orphaned member of the β -subunit subfamily of G proteins), form the so-called GTPase-Activating-Protein (GAP) complex. Modified from Koutalos Y and Yau K-W (1996) Regulation of light sensitivity in retinal rods. *Trends in Neurosciences* 19: 73–81.

the cGMP-gated channels close, but the Ca^{2+} efflux through the Na/Ca, K exchange continues, as a result of which the free Ca^{2+} in the outer segment decreases. This Ca^{2+} decrease triggers negative feedback on multiple targets in the phototransduction machinery, leading to an attenuation of the initial cGMP decrease induced by light, and hence reopening of some of the cGMP-gated channels. This negative feedback constitutes the key mechanism for active light adaptation by the photoreceptor, and is particularly important for cones because they function in bright light. The active, meta-II state of the pigment is deactivated by phosphorylation followed by binding of a protein called arrestin, which caps the pigment activity. After a delay, the meta-II decays into the inactive meta-III state and eventually splits into apo-opsin and all-*trans*-retinaldehyde (i.e., the pigment is bleached). The latter is reduced to all-*trans*-retinol (i.e., the corresponding alcohol), then leaves the photoreceptor to the neighboring retinal pigment epithelial cells, where all-*trans*-retinol is reisolomerized/reoxidized to 11-*cis*-retinaldehyde. The 11-*cis*-retinaldehyde returns to the rod and cone outer segments, where it recombines with opsin to form a functional pigment molecule again.

Retinal Nonrod/Noncone Photoreceptors

Very recently, a different class of retinal photoreceptors has been discovered. These are a small subset of retinal ganglion cells, third-order retinal neurons that send light signals to the brain via their axons (optic-nerve fibers). The activity of the great majority of retinal ganglion cells is synaptically driven by the second-order retinal neurons, which, in turn, receive inputs from rods and cones. About 1% of the ganglion cells, however, are also intrinsically photosensitive. They express the pigment, melanopsin, which makes these cells photosensitive (Figure 3). Light depolarizes these cells, leading to the firing of action potentials. The phototransduction mechanism underlying this depolarizing response is still unclear, although a phospholipase C (PLC) pathway is likely involved. Although most retinal ganglion cells convey light information for image-forming vision, such as used in the detection and recognition of objects, the intrinsically photosensitive ganglion cells convey light information mostly for nonimage-forming (accessory) visual functions, such as circadian photoentrainment and the pupillary light reflex. Accordingly, their axons project primarily to brain nuclei involved in these functions.

Most recently, it has been found that some horizontal cells in fish are also intrinsically photosensitive. This is presumably for fine modulation of retinal signal processing. Melanopsin (and possibly additional pigments) appears to be also the pigment underlying the intrinsic photosensitivity. The same may be true in birds.

Parietal-Eye Photoreceptor

The parietal-eye photoreceptor bears remarkable morphological similarity to rods and cones (especially cones). However, there are several interesting differences between them. First, even in isolation, the parietal-eye photoreceptor continues to respond to light after intense illumination, suggesting that

Figure 3 Immunofluorescent labeling of a flat-mounted rat retina with an antimelanopsin antibody. Green color shows the labeling. Stacked confocal images. Reproduced from Hattar S, Liao H-W, Takao M, Berson DM, and Yau K-W (2002) Melanopsin-containing retinal ganglion cells: Architecture, projections and intrinsic photosensitivity. *Science* 295: 1065–1070.

there is a chromophore-recycling system within the cell that allows autonomous pigment regeneration, a feature absent in rods and cones. Second, there appear to be two pigments in the same cell, optimally responding to blue and green light, respectively. The green pigment when active depolarizes the cell, whereas the blue pigment when active hyperpolarizes the cell. The phototransduction mechanism is very similar to that in rods and cones, except that, although the blue pigment activates a cGMP-phosphodiesterase, the green pigment inhibits it. Thus, there is a chromatic antagonism in a given cell. Depending on the relative intensities of green and blue light, the cGMP level rises or falls, causing the cGMP-gated channels to open or close, hence a depolarization or hyperpolarization. The exact function of the parietal eye is unclear, but it may have to do with informing the animal about the progression of the day.

Pineal Photoreceptors

In birds and fish, the pineal gland is intrinsically photosensitive. Morphologically, the pineal photoreceptors roughly resemble rods and cones. Light elicits a hyperpolarizing response from these cells, with an underlying transduction mechanism also similar to that in rods and cones. The pineal gland releases the hormone melatonin, with light curtailing this release. In mammals, the intrinsically light-insensitive pineal also releases melatonin; in this case, however, the curtailment of melatonin release by light is not direct, but indirect via the suprachiasmatic nucleus, a target of optic-nerve fibers.

Deep-Brain Photoreceptors

At least in birds, there is evidence that certain cells in the brain are intrinsically photosensitive. Also, immunocytochemistry and *in situ* hybridization studies suggest that opsin proteins are present in small populations/clusters of neurons in the diencephalon. No other details are known at present.

Glossary

CO₂-concentrating mechanism A biochemical (in terrestrial plants) or biophysical pump (in many aquatic photosynthetic organisms) which concentrates CO₂ around RuBP carboxylase-oxygenase (Rubisco) to reduce photorespiration.

Photorespiration The wasteful process by which glycolate 2-phosphate, which results from the oxygenation reaction of Rubisco, is recycled to the Benson–Calvin cycle.

Reaction center A multisubunit protein complex situated in the photosynthetic membrane containing the reaction center chlorophylls as well as other components involved in electron transfer, which together convert the energy of sunlight into a usable chemical form.

Photosynthetic Structures

Leaves contain many different types of cells, including stomata, which regulate gas exchange through the epidermis, and the photosynthetic palisade and mesophyll cells, which are thin walled and have abundant air spaces for the diffusion of gases. Chloroplasts are the organelles which carry out photosynthesis within these cells. The chloroplast has a double-membrane envelope, which regulates transport of metabolites and proteins with the cytosol. It contains thylakoids, a system of membranes, which, in turn, contain the components of photosynthetic light harvesting (including chlorophyll), electron transport, and adenosine triphosphate (ATP) synthesis. The thylakoids form sacs with an internal lumen. Thylakoid sacs can occur singly or in stacks, called grana, which resemble a pile of coins. The soluble phase of the chloroplast is the stroma, which contains enzymes of a wide range of biosynthetic processes (Figure 1).

Harvesting Light

Light Harvesting

The first step in photosynthesis is light absorption by pigments. Besides various types of chlorophyll, these pigments include carotenoids, and open-chain tetrapyrrole bilin pigments found in, for example, cyanobacteria. Chlorophyll is a pigment based on a tetrapyrrole ring, rather like hemoglobin, except that it contains magnesium rather than iron. The ring is linked to a long side chain. Chlorophyll absorbs blue and red light, while it transmits in the green, and hence appears green. In plants, two types of chlorophyll, *a* and *b*, increase the range of wavelengths absorbed. The light energy absorbed by chlorophyll molecules either can be lost as heat or fluorescence, or can be transferred between adjacent chlorophyll molecules by resonance transfer. Chlorophyll and carotenoids associate with proteins in light-harvesting complexes. The light-harvesting complexes have been crystallized from both bacteria and plants. A light-harvesting complex acts like an antenna, similar to a satellite dish, feeding photons into the reaction centers,

which contain a dimeric form of chlorophyll, where charge separation occurs. The concept of an antenna arose from the discovery in 1932, by Emerson and Arnold, that only one CO₂ molecule was produced from about 2500 chlorophyll molecules after a short flash of light.

At a higher level of organization, the leaf and its cells are also adapted to harvest light efficiently. In shade, the photosynthetic apparatus is spread out in large thin leaves, to increase the area of light capture and to allow light to penetrate adequately, and there is more light-harvesting chlorophyll per antenna. Within the leaf, epidermal cells can act to focus light, elongated palisade cells act as light guides, whereas mesophyll cells reflect light, acting like a hall of mirrors and increasing the distance that photons travel, thereby increasing the chance that they will be intercepted by an antenna complex.

Energy Capture

Reaction centers are multisubunit protein complexes situated in the photosynthetic membrane. These complexes contain the reaction center chlorophylls as well as other components involved in electron transfer. The reaction center is the core of the photosynthetic process, converting the energy of sunlight into a usable chemical form. Reaction centers carry out light-driven electron-transfer reactions that result in charge separation across the photosynthetic membrane. Rapid electron transfer to secondary acceptors is necessary to prevent recombination of these separated charges. There are two classes of reaction centers with different terminal electron acceptors, those with Fe₄S₄ clusters (type 1) and those with pheophytin/quinones (type 2). In plants, green algae, and cyanobacteria, both reaction centers are present (in photosystems 1 and 2, respectively), whereas photosynthetic bacteria have only one type of reaction center (e.g., type 1 in green sulfur bacteria and type 2 in purple bacteria). In plants, photosystem 2 contains a chlorophyll dimer which, when in the excited state (P680*), is an extremely strong reducing agent. An acceptor molecule, a quinone, Q, becomes reduced, leaving the positively charged chlorophyll dimer (P680⁺). This is an extremely strong oxidant, so strong that it can extract electrons from water.

Figure 1 Electron micrograph of a chloroplast from maize.

Water Oxidation

Water oxidation is a unique feature of photosystem 2. Water is the electron donor for photosynthetic electron transport. Each photon absorbed by P680 enables it to extract one electron from a manganese-containing enzyme, in an oxygen-evolving complex. Once four electrons have been extracted, this complex can, in turn, oxidize water, releasing O_2 to the atmosphere, as well as releasing $4H^+$ to the thylakoid lumen. Photosynthetic bacteria utilize other sources, such as H_2S or organic compounds, as electron donors.

Energy Dissipation and Reactive Oxygen Species

Although light is required for photosynthesis, too much light can be harmful. The generation of highly reactive intermediates in oxygenic photosynthesis can lead to the generation of reactive oxygen species. To protect the photosynthetic apparatus from oxidative damage, photosynthetic systems possess antioxidant systems that scavenge reactive oxygen species, as well as mechanisms that regulate photosynthesis to minimize their production. These mechanisms are particularly important in high light, when the absorption of light energy exceeds a plant's capacity for CO_2 fixation (e.g., when CO_2 uptake is limited by stomatal closure brought about by water stress). For example, besides acting as accessory pigments in the antenna, carotenoids also have a photoprotective role. When there is an excess of light energy, carotenoids can quench the excited triplet state of chlorophyll before it reacts with oxygen, forming destructive singlet-state oxygen. Carotenoids can also regulate energy flow in the antenna by dissipating excitation of the chlorophylls as heat (nonphotochemical chlorophyll fluorescence quenching). Energy dissipation is associated with the accumulation of the carotenoid, zeaxanthin, which is interconverted with another carotenoid, violaxanthin, in the xanthophyll cycle. Physical changes, such as chloroplast movements within cells and heliotropic leaf movements, can also reduce or enhance light absorption, and photorespiration can dissipate excess photosynthetic energy.

Electron Transport and ATP Synthesis

There are two photosystems, 1 and 2, involved in photosynthesis in plants, algae, and cyanobacteria. The structures of

Figure 2 The Z-scheme of photosynthetic electron transport, showing the mid-point redox potentials of electron donors, acceptors, and carriers.

both have been determined. In 1960, Hill and Bendall published the Z scheme, which describes how the two photosystems and the electron carriers are organized with respect to their redox potentials (Figure 2). Electrons from photosystem 2 reduce a number of intermediate electron carriers, such as plastoquinone (PQ), the cytochrome *b/f* complex (including the Rieske iron-sulfur center), and plastocyanin (PC). The reaction center of photosystem 1 (P700) receives its electrons from photosystem II via these carriers and thus oxidizes Q. Photosystem 1 reduces an initial acceptor, A_0 , then a series of Fe-S acceptors and ferredoxin (Fd, another iron-sulfur protein) and, finally, nicotinamide adenine dinucleotide phosphate (NADP) is reduced to NADPH. Electrons may also cycle around photosystem 1, leading to ATP generation, as also occurs in some photosynthetic bacteria.

Electron transport components are organized within the thylakoid membrane so that, as electrons flow from water to NADP, protons are transferred from the stroma to the thylakoid lumen (Figure 3). This is possible because the key component linking the two photosystems is PQ, which is a hydrogen carrier, carrying both an electron (e^-) and a proton (H^+). Electrons from photosystem II reduce PQ, together with protons from the stroma, while oxidation of PQ releases electrons to the cytochrome *b/f* complex and protons to the thylakoid lumen. This proton shuttle is driven by photosynthetic electron transport. Protons are also released to the thylakoid lumen when water is oxidized. These processes decrease the pH in the stroma (from pH 7 in the dark to pH 8 in the light) and acidify the lumen (to about pH 5). A pH gradient is therefore created, which is used to drive ATP synthesis (chemiosmosis). For each molecule of ATP synthesized, $4H^+$ move from the lumen to the stroma. Movement of protons through

Figure 3 Organization of photosynthetic electron transport within the thylakoid membrane, showing how proton production and translocation generate a proton gradient between the thylakoid lumen and the stroma.

the ATPase causes its central crankshaft-like core to rotate. This rotational movement causes conformational changes in the active sites of other subunits, which result in the synthesis of ATP from adenosine diphosphate (ADP) and Pi.

Carbon Fixation and Photorespiration

The chloroplast is one of the plant cell's most important factories. ATP and NADPH are utilized to drive biosynthetic processes in the chloroplasts, including the reduction of sulfate and nitrite and the synthesis of lipids and amino acids, in addition to CO₂ fixation. All these require an array of transporters at the chloroplast envelope.

Benson–Calvin Cycle

Although often termed the 'dark reaction' of photosynthesis, CO₂ fixation can only proceed in the light, both because it requires photosynthetically generated ATP and NADPH and because many of the enzymes which catalyze the process are themselves activated by light. The Benson–Calvin cycle (or reductive pentose phosphate pathway) is the only mechanism in plants and algae, which can catalyze the net fixation of CO₂, although some bacteria have an alternative mechanism. The Benson–Calvin cycle (Figure 4) was discovered in the early 1950s by Melvin Calvin and co-workers, who supplied algae, such as *Chlorella*, with ¹⁴CO₂. The first product of photosynthesis, containing 100% of the radioactivity at zero time, was a three-carbon compound, glycerate 3-phosphate (hence the term 'C₃' plants). The primary acceptor was identified as ribulose 1,5-bisphosphate (RuBP). The Benson–Calvin cycle comprises three phases: (1) carboxylation by RuBP carboxylase-oxygenase (Rubisco) – RuBP is a five-carbon sugar phosphate which is carboxylated to form two molecules of glycerate-3-P; (2) reduction of glycerate-3-P to triose-P (which requires ATP and NADPH); and (3) regeneration of the acceptor, RuBP, from triose-P in a sugar–phosphate shuffle, which

Figure 4 A simplified scheme for the Benson–Calvin cycle, showing the carboxylation of RuBP by Rubisco, reduction of glycerate 3-P to triose-P, and regeneration of the initial acceptor from triose-P.

requires ATP. Triose-P is a simple sugar phosphate produced by the Calvin cycle. Triose-P that is not needed for regeneration of RuBP can be either converted to starch in the chloroplast or exported to the cytosol, via the phosphate translocator, to make sucrose.

Photorespiration

Rubisco is an inefficient enzyme. It has a slow catalytic turnover rate, and about half the soluble protein in leaves is Rubisco, making it the most abundant protein in nature:

Rubisco also catalyzes a side reaction with oxygen, an inevitable consequence of its reaction mechanism. Rubisco evolved in the photosynthetic bacteria billions of years ago in an atmosphere, which was richer in CO_2 and depleted in O_2 in comparison with the present atmosphere. The ratio of oxygenation to carboxylation by Rubisco depends upon the relative concentrations of CO_2 and O_2 and oxygenation increases as the temperature increases. Photorespiration is the process by which two molecules of glycolate-2-P, which is not a metabolite of the Benson–Calvin cycle, are retrieved and converted into two molecules of an amino acid, glycine (C2), and then into one molecule of glycerate-3-P (C3). This involves shuttling of metabolites among the chloroplasts, cytosol, peroxisomes, and mitochondria. During this process, one-quarter of the carbon in glycolate-2-P is lost as CO_2 and ammonia are liberated. Photorespiration is therefore a wasteful process because it both reduces carbon gain and dissipates photosynthetic energy (because CO_2 is first fixed and released again). There is, therefore, a selection pressure on plants to reduce the rate of photorespiration by means of CO_2 -concentrating mechanisms, so as to improve their carbon economy. This is particularly strong when high rates of photorespiration are favored, as at high temperatures. However, a future doubling of ambient CO_2 will reduce photorespiration by about 50%, and it would be completely eliminated by a fivefold rise in atmospheric CO_2 .

CO_2 -Concentrating Mechanisms

C4 Photosynthesis

C4 plants include many tropical grasses and are among the world's most important crop species (maize and sugarcane). Although small in terms of total number of flowering plant species (3%), they constitute about 50% of the 10 000 grass species. Their productivity is high, and C4 grasses in savannah regions (15% of the Earth's vegetated surface) are responsible for about 20% of global photosynthesis. C4 plants have a distinctive leaf anatomy (Kranz anatomy), with chloroplast-rich bundle-sheath cells, which form a gas-tight cylinder surrounding the vascular bundle. A CO_2 pump (the C4 cycle) takes CO_2 from the mesophyll and transfers it into the bundle sheath, which contains Rubisco and the enzymes of the Benson–Calvin cycle (Figure 5). The process raises the concentration of CO_2 in the bundle sheath, and is sufficient to saturate Rubisco with CO_2 and to eliminate photorespiration. Like all pumps, the C4 cycle requires an input of energy in the form of ATP. Recently, two terrestrial plants have been shown to have single-celled C4 photosynthesis, a phenomenon only otherwise known in a few aquatic angiosperms and some diatoms.

The mechanism of photosynthesis in C4 plants was elucidated in the 1960s by Hatch and Slack in Australia. C4 plants are so called because the first product of CO_2 fixation is a C4 organic acid, oxaloacetate, formed by the carboxylation of phosphoenolpyruvate (PEP) by PEP carboxylase. The oxaloacetate is converted to other C4 acids (malate or aspartate) and transferred to the bundle sheath. Transport of metabolites between the mesophyll and bundle sheath occurs by diffusion via plasmodesmata. In the bundle sheath, the C4 acids are decarboxylated to generate CO_2 , and a C3 compound returns

Figure 5 A simplified scheme for the mechanism of C4 photosynthesis, showing how the C4 cycle shuttles C4 acids into to bundle sheath, where they are decarboxylated to raise the CO_2 concentration in the vicinity of Rubisco and thereby suppress photorespiration.

to the mesophyll. The mechanism of decarboxylation differs, with NADP-malic enzyme in the chloroplast (maize), NAD-malic enzyme in the mitochondria (millet), or PEP carboxykinase in the cytosol (e.g., guinea grass).

C4 plants are commonly found in warm- to high-temperature environments, such as tropical grasslands, where photorespiratory rates would be high in C3 plants. C4 plants have double the water-use efficiency of C3 plants because photosynthesis can operate at low intercellular concentrations of CO_2 , and hence at lower stomatal conductances. Nitrogen-use efficiency is also improved because Rubisco is used more efficiently, due to the suppression of photorespiration.

Aquatic Photosynthesis

The aquatic environment poses serious problems for the acquisition of CO_2 . First, the diffusion of CO_2 in water is 10 000 times slower than in air. Second, inorganic carbon is present in water as CO_2 , HCO_3^- , and CO_3^{2-} , the relative amounts of which depend upon the pH of the water. Most inorganic carbon in alkaline waters is therefore present as carbonate and bicarbonate. Photosynthesis by aquatic plants, algae, and phytoplankton may raise the local O_2 concentration and enhance photorespiration. Aquatic organisms (cyanobacteria, micro- and macro-algae, and aquatic angiosperms) have developed means of taking up dissolved inorganic carbon (CO_2 and HCO_3^-) actively from their environment. They can concentrate it internally around Rubisco in specialized structures, such as carboxysomes and pyrenoids, and thus suppress photorespiration.

Crassulacean Acid Metabolism

Leaves are faced with a difficult task. Leaf cells have thin walls and the intercellular spaces are saturated with water vapor.

As leaves assimilate CO₂ (5000 l of air are needed to manufacture 1 g of sucrose), they need to restrict the amount of water lost from the leaf via the stomata. Therefore, there is a conflict between the requirements for CO₂ fixation and water conservation. Crassulacean acid metabolism (CAM) is a photosynthetic adaptation to periodic water supply, occurring in plants in arid regions (e.g., cacti) or in tropical epiphytes (e.g., orchids and bromeliads). CAM plants close their stomata during the day and take up CO₂ at night, when the air temperature is lower. Water loss can be lowered by an order of magnitude. CAM occurs in between 5% and 10% of plants and is always associated with succulence, at least at a cellular level.

Although the biochemistry is similar to that of C₄ plants, two carboxylations are now separated in time rather than in space. Malic acid is synthesized from carbohydrates, via PEP carboxylase, at night, and is stored in the vacuole. During the day, malate is decarboxylated, via PEP carboxykinase or NAD (P)-malic enzymes in the cytosol, and CO₂ is refixed via the Benson–Calvin cycle and carbohydrates are reformed. This process occurs behind closed stomata. The internal concentration of CO₂ is raised as high as 10 000 ppm, which also suppresses photorespiration. CAM plants show a high degree of metabolic flexibility. Seedlings and well-watered plants may show little or no CAM and perform C₃ photosynthesis, opening their stomata during the day. This allows increased carbon gain during periods of water availability or during seedling establishment. Water or salt stress can then induce CAM, switching on gene expression for synthesis of the component enzymes.

Glossary

Calvin cycle, reductive pentose phosphate pathway, or photosynthetic carbon reduction cycle Series of reactions that reduce CO₂ into triose phosphate in the chloroplast from which sugars, amino acids, and other plant products are synthesized.

Chloroplast Organelle in which light reactions and Calvin cycle take place.

Feedback regulation Regulates carbon flow through the Calvin cycle in response to the demand for photosynthate in end-product synthesis. It can operate both at the level of recycling inorganic phosphate back to the Calvin cycle and

at the level of sugar-regulated gene expression of the photosynthetic apparatus.

Feedforward regulation Enables the Calvin cycle to respond sensitively to light by affecting the synthesis of Calvin cycle enzymes and their activity.

Light reactions They drive electron flow which leads to the reduction of nicotinamide adenine dinucleotide phosphate (NADP) to reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and synthesis of adenosine triphosphate (ATP) necessary for the operation of the Calvin cycle.

Light Provides Energy (Adenosine Triphosphate) and Reducing Power (Reduced Nicotinamide Adenine Dinucleotide Phosphate) for CO₂ Fixation

Photons in the range of 400–700 nm – except green light, which is reflected – drive photosynthesis through provision of adenosine triphosphate (ATP) and reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). Light also regulates the Calvin cycle by the thioredox system (see later). Photons interact with electrons in the chlorophylls of light-harvesting antenna in thylakoid membranes of chloroplasts. There are two light-absorbing photosystems that cooperate in the reduction of nicotinamide adenine dinucleotide phosphate (NADP) by electrons derived from water. Energy is passed from these to reaction centers of photosystem II, where electrons are excited and passed to an acceptor and down an electron transport chain to photosystem I. Electrons and protons pass to NADP, yielding NADPH. The open reaction center of photosystem II is filled with electrons from water, from which O₂ is evolved. A pH gradient across the thylakoid membrane from H⁺ accumulation in the thylakoid lumen provides the impetus for ATP synthesis by ATP synthase in photophosphorylation (Figure 1).

The Path of Carbon in Photosynthesis

The sequence of reactions that fix CO₂ into triose phosphate using ATP and NADPH from these light reactions was determined using C14 radioisotopes by Melvin Calvin and colleagues, for which the Nobel prize for chemistry was awarded. This sequence of reactions is now known as the Calvin cycle, reductive pentose phosphate pathway, or photosynthetic carbon reduction cycle. It consists of three distinct phases. First, the fixation of CO₂ into 3-phosphoglyceric acid (3-PGA) (carboxylation). Second, the reduction of 3-PGA into

the triose phosphate, glyceraldehyde-3-phosphate (GAP). The triose phosphate is exported to the cytosol for sucrose synthesis or remains in the chloroplast for starch synthesis or the other biosynthetic reactions that occur there. Five-sixths of the carbon fixed, however, is retained within the cycle itself to allow regeneration of the CO₂ acceptor, ribulose 1,5-bisphosphate (RuBP), in the third, regenerative phase of the cycle (Figure 2).

Carboxylation Phase

Carboxylation is catalyzed by ribulose bisphosphate carboxylase/oxygenase (Rubisco), which can constitute up to 50% of the soluble protein in a leaf and is probably the Earth's most abundant protein. The combination of CO₂ with RuBP, a five-carbon compound, yields two molecules of the three-carbon compound 3-PGA. Many enzymes will bind to molecules in addition to the ones they have primary affinity for, if they are present at high enough concentrations. Present-day atmospheric O₂ concentration is 1000 times higher than that of CO₂, and oxygenation of RuBP also occurs. This produces one molecule of 3-PGA and one molecule of phosphoglycolate (glycolate 2-P). The formation of phosphoglycolate represents carbon lost to the Calvin cycle and a series of reactions serve to return this carbon by converting phosphoglycolate to 3-PGA in a process termed as 'photorespiration' because CO₂ is evolved (Figure 1). These reactions involve the peroxisome where glycolate is converted into glycine, and mitochondria where glycine is converted into serine where CO₂ and ammonia are evolved. Serine then returns to the peroxisome for conversion to 3-PGA and exports back to the chloroplast. Ammonia is reassimilated through a reaction with glutamate and ATP to form glutamine catalyzed by glutamine synthetase in chloroplasts. Glutamine synthetase then catalyzes the formation of glutamate from glutamine and α -ketoglutarate. Oxygenation

Chloroplast

Figure 1 Schematic representation of photosynthetic metabolism summarizing the principal components of light reactions, CO₂ fixation into the Calvin cycle, photorespiration, and the synthesis of end products (sucrose and cell wall). Light causes feedforward regulation of the Calvin cycle. Feedback regulation by carbon fixed in photosynthesis occurs through regulation of the protein kinase, SnRK1.

of Rubisco and the retrieval of carbon from phosphoglycolate are wasteful of carbon and ATP and are also costly in terms of investment in the catalytic machinery required. Early evolution of Rubisco occurred when there was no oxygen in the atmosphere. When oxygen appeared more than a billion years later, the complexity of the Rubisco protein may have made it too difficult to eliminate oxygenase activity linked to phosphoglycolate production.

Supplementary Carboxylation Pathways – C₄ and Crassulacean Acid Metabolism

Some plants have evolved a supplementary carboxylation reaction catalyzed by phosphoenolpyruvate carboxylase where minimal oxygenation occurs. Such plants are known as C₄ plants because the first products of CO₂ fixation are carboxylic acids (oxaloacetic acid and malic acid) containing four carbon atoms. A high concentration of CO₂ generated from the decarboxylation of these acids at the site of the Calvin cycle minimizes the oxygenation reaction of Rubisco, and hence suppresses photorespiration. Other specialized plants known as Crassulacean acid metabolism (CAM) plants fix CO₂ into C₄

acids at night, which are then decarboxylated during the day. These metabolic adaptations of C₄ and CAM ensure a high daytime intercellular CO₂ concentration, which in addition to the benefit of maximizing carboxylation maintains a small stomatal aperture, conserving water, an overriding selection force in some environments. In CAM plants, stomata can be shut for much of the day and is observed in more extreme xerophytes such as cacti and succulents. The C₄ pathway is a major evolutionary success accounting for about a quarter of terrestrial CO₂ fixation. C₄ plants dominate tropical grasslands and savannahs, and include the important crops – sugarcane, maize, and sorghum.

Reduction Phase

The 3-PGA produced in the carboxylation phase (and returned from photorespiration) is reduced to triose phosphate, GAP, in two steps. The first, a phosphorylation step, requires ATP. The 1,3-bisphosphoglycerate formed is then reduced with NADPH to GAP. The high ATP and NADPH concentrations associated with photosynthesis shift these reactions in favor of triose phosphate.

Figure 2 Calvin cycle of reactions that incorporate CO_2 into triose phosphate and which regenerate ribulose-1,5-bisphosphate (Ru1,5BP) for continued CO_2 fixation. Numbers after compounds indicate number of carbon atoms. 3-PGA, 3-phosphoglyceric acid; 1,3 BPGA, 1,3 bisphosphoglyceric acid; GAP, glyceraldehyde-3-phosphate; DHAP, dihydroacetone phosphate; F1,6BP, fructose-1,6-bisphosphate; F6P, fructose-6-phosphate; E4P, erythrose-4-phosphate; S1,7BP, sedoheptulose-1,7-bisphosphate; S7P, sedoheptulose-7-phosphate; R5P, ribose-5-phosphate; Ru5P, ribulose-5-phosphate; Xu5P, xylulose-5-phosphate; Rubisco, ribulose-1,5-bisphosphatase; FBPase, fructose-1,6-bisphosphatase; SBPase, sedoheptulose-1,7-bisphosphatase; PRK, phosphoribulokinase.

Regeneration Phase

Carbon leaves the Calvin cycle for the synthesis of other products, such as triose phosphate for the synthesis of sucrose in the cytosol. Five-sixths of the carbon fixed, however, is retained within the cycle itself to resynthesize the acceptor molecule for CO_2 fixation, RuBP to keep the cycle going. In this series of reactions, five trioses are converted into three pentoses. The first part involves the conversion of GAP to fructose-6-phosphate (F6P). Then the carbon atoms in F6P, GAP, and dihydroxyacetone phosphate are rearranged into the pentose, ribulose-5-phosphate (Ru5P). In the final step, Ru5P is converted into RuBP in an ATP-requiring step. Similar to the rest of the cycle, this phase is highly regulated and can strongly affect the ultimate rate of CO_2 fixation. An important branch point in this segment of the cycle, catalyzed by transketolase links primary and secondary metabolism. The substrates and products of transketolase can supply carbon (erythrose-4-phosphate) for the synthesis of aromatic amino acids and phenylpropanoids (compounds important for flavor, texture, and color), nucleotide synthesis (R5P), and starch (F6P), in addition to the regeneration of RuBP.

Regulation of the Calvin Cycle

Metabolic regulation enables the balance between substrate and product of enzyme-catalyzed reactions to be maintained

so that ordered metabolic flow can occur in response to developmental requirements and environment. The Calvin cycle is regulated by light, which ensures its temporal separation from other reactions, such as the oxidative pentose phosphate pathway, also present in the chloroplast stroma, which would compete for the same substrates. Light regulates the cycle through provision of ATP and NADPH, which in turn regulate those steps dependent on them. Light also causes an increase in the pH of the chloroplast stroma to 8, the pH optimum for Calvin cycle enzymes. Pumping of protons into the thylakoids is also coupled with flow of magnesium necessary for enzyme activity into the stroma. A further way that light regulates the cycle is through photosynthetic electron transport. Reducing equivalents from photosystem I via ferredoxin–thioredoxin reductase reduce the thiol groups of GAP dehydrogenase (GAPDH), fructose-1,6-bisphosphatase (FBPase), sedoheptulose-1,7-bisphosphatase (SBPase), and phosphoribulokinase (PRK), increasing their activity. The net effect of the ferredoxin–thioredoxin system is the upregulation of the Calvin cycle in the light and downregulation in the dark, whereas the oxidative pentose phosphate pathway and glycolysis are regulated in the opposite manner in response to light and dark. Rubisco is activated by CO_2 and magnesium in a process called carbamylation, a process promoted by an activating protein, Rubisco activase. Rubisco activase also facilitates the release from the active site of Rubisco of sugar phosphates, such as RuBP and 2-carboxyarabinitol 1-phosphate,

a transition state analog of the carboxylation reaction of Rubisco. Rubisco activase is controlled in turn by ATP/adenosine diphosphate (ADP) ratio and is necessary for high rates of photosynthesis. Enzymes of the Calvin cycle are associated as enzyme complexes. For example, GAPDH and PRK are linked by the protein CP12. The precise role of the association of this complex is not yet known, but through aggregation into a supramolecular complex is likely to play a specific role in light/dark regulation.

Are Some Calvin Cycle Enzymes More Important in Regulating Carbon Flux than Others?

The equilibrium position of reactions catalyzed by Rubisco, NADP-GAP dehydrogenase, SBPase, FBPase, and PRK, because of their regulation, lies very much in favor of the end product. These enzymes are termed as irreversible enzymes because of the large amount of energy that would be required to reverse the reaction. Such enzymes have traditionally been seen as key enzymes because once carbon has passed through the reaction catalyzed by them it cannot return. Since the late 1980s, genetic modification has enabled individual enzymes to be targeted through the use of antisense RNA to decrease the synthesis of target enzyme. Lines of transgenic plants exhibiting progressive decreases in activity of an enzyme have enabled metabolic control analysis to be undertaken and flux control coefficients for individual enzymes assigned. For the Calvin cycle a change in enzyme activity can then be related to flux through the pathway by measuring CO₂ uptake by leaves using infrared gas analysis. The flux control coefficient is given as $C = \delta J/J$, where J is the original flux and δJ the changed flux. This coefficient can also be written as $C = \delta E/E$, where E is the original enzyme activity and δE the changed enzyme activity.

Therefore, if a 50% decrease in enzyme activity achieves a 25% decrease in CO₂ uptake, then the flux control coefficient is 0.5 (25/50); essentially, half the control of the pathway resides with that enzyme. If a 50% decrease achieves no change in flux, then the flux control coefficient is zero and the enzyme is in excess under those conditions. Over the course of a day, and during the life cycle of a plant, an enzyme may exhibit a range of flux control coefficients. Variation during the course of a day will be caused largely by changes in illumination, whereas over the life cycle by nitrogen availability and changes in light environment. Both light and nitrogen affect the amount of enzyme synthesized, and light also affects enzyme activity to different extents for different enzymes, so relative contributions to flux control change. Other aspects of environment, for example, temperature and phosphorus nutrition, are also influential.

Calvin Cycle Enzymes That Most Limit Flux

The first enzyme for which detailed flux control analysis was conducted using transgenics was Rubisco. Quite surprisingly at the time, in view of the perceived importance of this enzyme, the first data showed that removing half of it with

antisense resulted in little change in CO₂ fixation. However, when plants were grown at high light conditions, the flux control coefficient rose and, combined with low nitrogen, could reach 0.8. Rubisco is the enzyme that imposes the greatest potential limitation of Calvin cycle carbon fixation. SBPase is another enzyme with a potentially high flux control coefficient at high light. A major surprise was that non-regulated equilibrium enzymes, aldolase and transketolase, could have flux control coefficients around 0.3 under high light conditions. Other enzymes in the cycle when decreased up to 50% have showed no large impact on flux. The most extreme example of this is PRK, where a decrease up to 85% has no impact on CO₂ fixation. However, the flux control coefficient for this enzyme could increase to 0.25 if plants grown in shady conditions were suddenly exposed to high light.

The important message to come from this work is that both highly regulated and unregulated equilibrium enzymes could control flux, and the control exerted by individual enzymes varies according to the conditions. The work supported the von Caemmerer and Farquhar 1981 model, which proposed that photosynthesis was colimited between carboxylation (Rubisco activity) and the capacity to regenerate RuBP. Control was seen as poised between carboxylation and regeneration, but under saturating light, the balance would shift toward Rubisco and under low light toward regeneration. The research using antisense confirmed this assumption and gave useful indications as to which enzymes in the regeneration phase would be most likely to increase rates of CO₂ fixation if their activities could be increased. Thus, there would most likely be benefit if one or more of activities of SBPase, aldolase, or transketolase could be increased. Increasing amounts of Rubisco may be problematic because of the large nitrogen investment required.

Genetic Modification of Photosynthesis to Improve Growth and Yield

Direct Targeting of Calvin Cycle

In support of the findings of flux control analysis, expression of a bifunctional SBPase/FBPase from a cyanobacterium resulted in increased photosynthesis and biomass production. This was the first report of an increase in activity of one or more Calvin cycle enzymes benefiting photosynthesis and biomass production. There is also evidence that overexpressing the plant SBPase improves photosynthetic rates. Improved photosynthesis has also been achieved through expressing a cyanobacterial gene in plants involved in HCO₃⁻ accumulation, which releases CO₂ within the leaf for CO₂ fixation and hence improves carboxylation. Attempts are being made to improve crop productivity with superior forms of Rubisco from algae and through introduction of the C4 pathway. These former targets constitute direct targeting of the Calvin cycle. Another way to potentially increase CO₂ fixation is through targeting mechanisms that use the reduced carbon produced in photosynthesis downstream of the Calvin cycle. It has been known that the use of carbohydrate can regulate photosynthesis through the so-called feedback mechanisms. If such

mechanisms could be targeted this may represent a means to increase photosynthesis.

Feedback Regulation of the Calvin Cycle

In addition to the sophisticated control mechanisms that relate CO₂ fixation to light availability (feedforward regulation), feedback mechanisms relate Calvin cycle activity to the demand for the end products of photosynthesis. Inorganic phosphate (P_i) is a component of phosphorylated intermediates in pathways and is liberated when end product, for example, sucrose, is synthesized (sucrose contains no P_i). This recycling of P_i is necessary to ensure that metabolic flow can continue. Photophosphorylation and ATP synthesis are particularly sensitive to P_i supply. Slow recycling of P_i caused by slow end-product synthesis at low temperature, for example, can restrict the recycling of P_i and so limit photosynthesis.

Demand for end product is also determined by the genetic potential of the plant for growth and by other environmental factors, particularly nitrogen, which facilitates high growth rates. The assimilation of nitrogen into amino acids requires carbon skeletons derived from triose phosphates supplied by the Calvin cycle. An impairment of nitrogen supply slows growth, which can lead to a buildup of sugar in leaves, because photosynthates are no longer being used in growth and nitrogen assimilation. It was shown in 1990 that seven maize photosynthetic genes were repressed by glucose or sucrose in a maize protoplast system. Further evidence of control of photosynthetic gene expression by sugars has been obtained where sugars were made to accumulate in leaves due to genetic modification, environmental treatments (high CO₂ and low N₂, in particular), and through direct feeding of sugars to leaves. There have been advances recently in understanding mechanisms through which sugars regulate photosynthetic gene expression. One such mechanism involves a protein kinase called sucrose nonfermenting-1-related protein kinase 1 (SnRK1) of the sucrose nonfermenting-1 (SNF1)-related group of conserved protein kinases, found in all eukaryotes that includes adenosine monophosphate (AMP)-activated protein kinase (AMPK) of mammals and SNF1 of yeast. These kinases are activated by low-energy supply through AMP/ATP ratio and inactivated by reduced carbon – glucose (yeast), glycogen (mammals), or trehalose-6-phosphate (plants). Under conditions of low energy and low carbon availability, these protein kinases regulate processes at the level of gene expression and through regulation of enzyme activity by phosphorylation. They prevent starvation by inhibiting processes that consume ATP, such as biosynthetic processes (anabolism), and through activating processes that mobilize carbon and energy such as carbohydrate, protein, and lipid breakdown (catabolism). In plants, photosynthesis is also upregulated and growth is inhibited by active SnRK1 (Figure 1). This is an important means through which plant growth and development are regulated by carbon and energy supplied by photosynthesis, and means of regulating photosynthesis itself in the context of whole plant carbon and energy balance. These protein kinases are indispensable for the growth and survival of plants and their importance is increasingly being appreciated in the healthy functioning of all organisms.

Photosynthetic CO₂ Fixation of Whole Plants

It is clear that photosynthesis is regulated locally not only by factors such as light, but also by more distant effects at the whole plant level. This is important, as we have seen for feedback regulation, where slow use of carbon in growing regions can lead to feedback regulation by accumulation of sugars in leaves. In terms of the relationship between photosynthesis and productivity, regulation of photosynthesis must be considered at the whole plant level. Stomatal density of leaves can also be controlled by long-distance signals. Mature leaves detect CO₂ concentration, which controls the stomatal development of young leaves. Leaf area is another important consideration. A central strategy of photosynthetic regulation of whole plants is to balance photosynthetic rate of leaves with the overall leaf area of the plant. Surveys of variations in photosynthesis per unit leaf area of many crops demonstrate a negative relationship with leaf area. Many environmental factors, particularly light, and the genetic makeup of the plant determine the trade-off between photosynthetic rate of individual leaves and leaf area. For example, plants grown in low light invest in larger leaf area to maximize light interception rather than by high investment of photosynthetic machinery per unit leaf area. Growth rate and productivity are more closely related to leaf area than the photosynthetic rate of individual leaves. This is reflected in crop breeding for yield, which has increased leaf area often at the expense of photosynthetic rate. Large leaf area combined with use of fertilizers and control of pests and diseases has maximized photosynthesis per unit of land for high crop yields. Improvements in yields in this way may be reaching a limit, so advances in improvement of photosynthetic rate combined with large leaf area may be the way forward to increasing photosynthesis and for future productivity gains. The complexity of photosynthetic regulation at the pathway and whole plant level show that there are many things to consider in trying to genetically engineer photosynthesis and productivity. However, improved understanding of the regulation of photosynthesis provides room for optimism.

Glossary

Chloroplast Organelle of the plant cell, where photosynthesis takes place.

Electron donor/acceptor Molecules that donate or accept electrons in a redox reaction.

Electron transfer chain Sequential arrangement of pigments within the PS I, which transport the electron across the membrane.

Excitation energy transfer Transfer of the energy absorbed by the antenna pigments to the site of charge separation.

Photosystem I and II Large membrane protein complexes that perform the first reaction of energy conversion, the light-induced charge separation.

Thylakoid Membrane system, located inside the chloroplasts. The site where the proteins of the electron transfer chain are located and the primary processes of photosynthesis take place.

Definition

Photosystem I is a large membrane protein complex involved in the process of oxygenic photosynthesis, catalyzing the light-induced transmembrane electron transfer from plastocyanin or cytochrome *c*₆ to ferredoxin or flavodoxin.

Introduction

Oxygenic photosynthesis, catalyzed by plants, algae, and cyanobacteria, is the major process on Earth that converts light energy into chemical energy. It provides the major energy source for all higher life on the Earth and changed the atmosphere of planet Earth 2.5 billion years ago by using water as an electron source, leading to the evolution of oxygen. The light reactions of photosynthesis are catalyzed by two large membrane protein complexes, photosystem I and II (PSI and PSII), which act in series and are coupled by the cytochrome *b*₆*f* complex. PSI catalyzes the light-induced transmembrane charge separation across the photosynthetic membrane from plastocyanin or cytochrome *c*₆, located at the inside of the photosynthetic membrane (lumen of the thylakoids), to the soluble electron carrier protein ferredoxin, located at the outside (stroma or cytosolic side) of the thylakoids. The electrochemical gradient formed across the photosynthetic membrane by the light reactions in PSI and PSII drives synthesis of adenosine triphosphate (ATP) by the ATP synthase. The electrons are finally used for reduction of hydrogen, stored in the form of nicotinamide adenine dinucleotide phosphate and ATP, which are used for CO₂ fixation in the Calvin cycle.

Structure and Function of PSI: Overview

PSI is a large protein complex. In cyanobacteria, it is a trimer with a molecular weight of 1 million daltons. One monomer of PSI consists of 12 proteins and 127 cofactors. The structure of cyanobacterial PSI was determined at 2.5 Å resolution. It is shown in [Figure 1\(a\)](#).

The Cofactors

The cofactors are essential for the function of light absorption, energy transfer, and electron transfer. One functional unit of PSI contains 96 chlorophylls, the pigments that give plants their green color. The chlorophylls play a vital role in light absorption, energy transfer, and catalyze the primary charge separation and electron transfer reactions. The second prominent cofactors are 22 carotenoids, orange molecules, which serve as additional antenna pigments and protect PSI from photodamage under high light conditions. In addition to the chlorophylls and carotenoids, PSI contains three [4Fe4S] clusters and two phylloquinones, which are involved in electron transfer as well as four lipids and one Ca²⁺ ion, which play major structural roles.

The Proteins

The most important proteins in PSI are the two large protein subunits PsaA and PsaB. They form the functional and structural core of PSI and harbor all membrane intrinsic cofactors of the electron transport chain as well as 79 of the 90 antenna chlorophylls. The core of PSI consists of 10 transmembrane helices of PsaA and PsaB that surround the electron transfer chain like a fence. This core is represented by the five C-terminal transmembrane helices of PsaA/B. This part of PSI shows some structural but no sequence homologies to the core subunits of PSII and the purple bacterial reaction center (RC), which gives a hint that the photoreaction centers may all have evolved from a common ancestor. This heart of PSI is flanked on both sides by six transmembrane helices that correspond to the N-terminal antenna domain of PsaA/B (see [Figure 1\(c\)](#)). This antenna domain of PSI shows homologies to the major antenna proteins of PSII, fueling the suggestion that the large subunits of PSI, PsaA and PsaB, may have evolved by gene fusion of an ancient RC protein with an antenna protein. Seven small membrane intrinsic subunits surround the PsaA/B core of PSI. These small subunits, which contain only one to three transmembrane helices each, stabilize the antenna

Figure 1 Photosystem I (PSI) from *Thermosynechococcus elongatus*. (a) View on a PSI trimer as seen from the cytosolic side. The protein subunits of one PSI monomer are marked. Nine of 12 subunits of a monomer are membrane intrinsic, with the largest subunits PsaA and PsaB among them. The three membrane-extrinsic subunits PsaC, PsaD, and PsaE form a stromal hump, and black circles mark their main bodies in the image. Note that PsaD forms a clamp across PsaC, which has not been marked. (b) The core-antenna network of a PSI trimer. Chlorophylls are shown in green, except those in the electron transfer chain, which are depicted in blue. Carotene molecules are orange. The transmembrane helices of PsaA and PsaB have been numbered from N-terminus to C-terminus for orientation.

system and mediate trimerization of PSI. While the PsaA/B core of PSI is highly conserved between plants, algae, and cyanobacteria, the small membrane extrinsic subunits show variations between different photosynthetic kingdoms. In cyanobacteria, trimerization is mediated by subunits PsaL, I and M, while one of the additional plant specific subunit, PsaH, binds to PsaL and maintains PSI in a monomeric state in higher plants and green algae, where the PSI monomer is flanked on one site by four peripheral light-harvesting complexes I (LHCI), Lhca1-4. The structure of PSI from pea has been solved as a supercomplex with four LHCI proteins bound

to a monomeric PSI. The structure of this supercomplex is shown in Figure 2.

The soluble electron carrier proteins plastocyanin/cytochrome c_6 dock to PSI at its luminal site. Cytochrome c_6 is very likely the evolutionary older electron donor to PSI and can be found in most cyanobacteria and algae, some of which also contain plastocyanin, while in plants plastocyanin serves as the sole electron donor to PSI. The docking site for cytochrome c_6 /plastocyanin is located at a relatively shallow, 20-Å-deep luminal indentation of PSI, which guides the electron donor proteins to the docking site in close proximity to

Figure 2 PSI from *Pisum sativum* as seen from the stroma. The core subunits (PsaA, PsaB, PsaC, PsaD, PsaE, PsaF, PsaI, PsaJ, PsaK, and PsaL) closely resemble their cyanobacterial counterparts, shown in [Figure 1\(a\)](#). The plant-specific subunits, PsaG and PsaH, play roles in binding LHCI and LHCII, respectively. The subunit PsaR has been putatively assigned and awaits further characterization.

P700, which in turn catalyzes the primary charge separation. This docking site only involves PsaA and PsaB and is mainly hydrophobic in cyanobacteria. However, an extension of a luminal helix of the subunit PsaF provides an additional interaction site in plants and algae that allows for a more stable complex formation by electrostatic interactions.

While the luminal side of PSI is relatively flat, it extends the membrane by 90 Å at the stromal side, a structural feature which is often referred to as the stromal hump. Three membrane extrinsic subunits, PsaC, PsaD, and PsaE, form the stromal hump which provides the docking site for the stromal electron carrier ferredoxin or flavodoxin. The latter replaces ferredoxin under iron deficiency. PsaC, which is located in the center of the hump, is the most important of the three extrinsic subunits, as it carries the terminal FeS clusters, named F_A and F_B , which transfer the electron from PSI to ferredoxin/flavodoxin. PsaE and PsaD stabilize the stromal hump and mediate docking of ferredoxin/flavodoxin. The stromal hump with the putative docking site is shown in [Figure 3](#).

The Electron Transfer Chain

The electron transport chain of PSI is well conserved between plants and cyanobacteria and consists of six chlorophylls, two phylloquinone molecules, and three [4Fe4S] clusters. The cofactor arrangement is shown in [Figure 4](#). The organic cofactors are arranged in the form of two branches, which show a twofold axis running through the first FeS cluster F_X . They are named A- and B-branch, which refers to the preferential coordination of the cofactors by the two large subunits, PsaA and PsaB. The electron transfer starts with the primary charge

Figure 3 The cytosolic subunits PsaC, PsaD, and PsaE from *T. elongatus*. PsaC encloses two iron-sulfur clusters, F_A and F_B . PsaD forms a clamp across PsaC. The iron-sulfur cluster F_X , which is situated between the large membrane-intrinsic subunits PsaA and PsaB, is shown for orientation.

separation. Excitation energy transfer from the antenna chlorophylls leads to excitation of P700 to the excited state P700*, which catalyzes the primary charge separation. P700 is very likely represented by the first pair of chlorophylls, which consist of one chlorophyll *a* molecule in the B-branch and the C13 epimer of chlorophyll *a* in the A-branch. However, there is also spectroscopic evidence that P700* may be delocalized over more than just two chlorophylls and that charge separation may also be able to start from one of the accessory chlorophylls. The electron is transferred along either the A- or B-branch over a chain of electron carriers that include the second and third symmetry-related pairs of chlorophylls, the phylloquinones, and the FeS cluster F_X , until it reaches the terminal FeS clusters F_A and F_B , which are coordinated by PsaC. From F_B , the electron is finally transferred to ferredoxin. The nature and distribution of electrons along the two branches is an

Figure 4 The electron transfer chain (ETC) of PSI. After charge separation at P_{700} , an electron moves along one of the branches of chlorophylls and phyloquinones and further along the iron–sulfur clusters, until the iron–sulfur cluster F_B reduces the soluble electron acceptor Ferredoxin.

open and vividly discussed topic of current research. Results of site-directed mutagenesis in combination with optical and electron paramagnetic resonance (EPR) spectroscopy evidence show that both electron transfer branches are active and that the ratio of A- versus B-branch electron transfer varies between organisms. There is also evidence that the electron transfer step from the phyloquinones to F_X is rate limiting for electron transfer in PSI, with the B-branch electron transfer step from the phyloquinone to F_X being 10 times faster than the electron transfer along the A-branch. The reason for this difference in electron transfer rates is under investigation. One explanation is the presence of two different lipids in close proximity to the electron transport chain. In the faster B-branch, this lipid is a neutral galactolipid, while at the A-branch a negatively charged phospholipid is located in proximity to the phyloquinone, which could increase the activation energy barrier for the electron transfer between the phyloquinone and F_X at the A branch. The first FeS cluster F_X is a rare example of a $4Fe_4S$ cluster coordinated by two different proteins. Two cysteine residues of PsaA and PsaB coordinate the four Fe atoms in the $[4Fe_4S]$ cluster F_X . F_X is located at the twofold axis that relates PsaA and PsaB. In addition to its role in electron transfer, F_X also plays a very important role in the assembly of PSI. From F_X , the electron is transferred subsequently to the FeS clusters F_A and F_B , located in the extrinsic subunit PsaC. PsaC shows strong structural homology to soluble ferredoxins that contain two $[4Fe_4S]$ clusters and it has therefore been proposed that it may share the same evolutionary roots with these soluble electron carriers, where a previously soluble protein became part of the larger multi-protein complex of PSI. Further evidence for this hypothesis is provided by the comparison of PSI with primitive anaerobic homodimeric photoreaction centers found in heliobacteria and green sulfur bacteria. The photoreaction centers in these organisms consist of a homodimeric RC core, where an extrinsic protein containing two $4Fe_4S$ clusters is only weakly attached.

The Antenna System

The core-antenna system of PSI in cyanobacteria consists of 90 chlorophyll *a* molecules and 22 carotenoids per monomer. The antenna systems of the three monomers in the PSI trimer (see [Figure 1\(b\)](#)) are tightly interconnected so that excitation energy transfer also involves transfer of excitation energy from one monomer to the next. The chlorophylls form a clustered network, where nearly all chlorophylls are located at distances <15 Å to the next neighbor, which ensures high efficiency of excitation energy transfer. The carotenoids are distributed all over the antenna system. They serve two functions. They serve as additional antenna pigments and are very important for photo-protection, as they quench dangerous triplet states of chlorophylls and dissipate the excess energy as heat, thereby preventing the formation of reactive oxygen species.

The quantum efficiency of the excitation energy transfer from the antenna to P_{700} is $>99.9\%$ at room temperature. This core-antenna system has been highly conserved over 1.5 billion years of evolution as more than 90% of the core-antenna chlorophylls have the same orientation and location in plant and cyanobacteria.

Most chlorophylls of the core-antenna system are coordinated by the large subunits PsaA and PsaB. It has been proposed that these subunits have evolved by a gene fusion between an antenna protein with the protein that coordinated the electron transfer chain, a situation that can still be found in PSII, where both functions are found on separate protein chains. The fusion of the two proteins allowed for a development of a very efficient antenna system in PSI, which contains a joint RC and antenna system. The whole core-antenna system is, structurally and functionally, tightly coupled to the RC core. The chlorophylls of the core antenna can be divided nearly half and half: (1) into antenna chlorophylls that are coordinated by the N-terminal six-transmembrane helices of PsaA/PsaB and the peripheral subunits and (2) the chlorophylls that are located close to the RC core which are coordinated by the C-terminal five-transmembrane helices of PsaA and PsaB. These include the two so-called ‘connecting’ antenna chlorophylls, which are coordinated by helix 11 and are located inside the fence of the 10 C-terminal transmembrane helices that surround the RC core of PSI.

The major function of the small subunits is to stabilize the core-antenna system and provide a connection to interact with peripheral antenna systems. The subunits that coordinate core-antenna chlorophylls are PsaI, PsaJ, PsaK, PsaL, and PsaX. It should also be noted that one of the phospholipids in PSI coordinates an antenna chlorophyll.

In plants, PSI is a monomer and forms a complex with four tightly bound peripheral antenna proteins: the LHCs Lhca1, Lhca2, Lhca3, and Lhca4. The structure of the PSI–LHCI complex of pea has been determined at 3.4 Å and reveals the architecture of the complex (see [Figure 2](#)). The Lhca proteins flank the PSI core at the site of the complex where subunits PsaF and PsaJ are located. The PSI–LHCI complex contains a total of 173 chlorophylls: 109 chlorophylls are assigned to the core of PSI, 55 chlorophylls are coordinated by the LHCI proteins, while nine chlorophylls are located at the interface between the LHCI antenna proteins and the core-antenna system of PSI. Plants undergo state transitions, during which the

light-harvesting complex II (LHCII) proteins can move from PSII to PSI. There is evidence from electron microscopic studies that the LHCII trimer may dock to PSI at the opposite site to the LHCI belt to the plant-specific subunit PsaH, which is located in close vicinity to PsaL.

Most cyanobacteria contain genes for two different peripheral antenna systems. Under nutrient replete conditions, phycobilisomes, which are large membrane extrinsic antenna complexes, serve as peripheral antenna systems for both PSI and PSII. They can move very fast between the photosystems in response to changing light conditions. In addition, many cyanobacteria also contain a membrane intrinsic antenna system consisting of rings of the IsiA protein that surround the PSI trimer. These IsiA rings dramatically increase the size of the antenna system in PSI under conditions of iron deficiency, which is the dominant environmental limitation in most aquatic environments. The system contains up to two rings of IsiA proteins surrounding the PSI core, with the inner ring consisting of 18 and the outer ring of 25 IsiA subunits. These 43 extra antenna proteins lead to a size of the PSI–IsiA double ring complex of 3.2 million daltons, which includes 855 chlorophyll molecules. The chlorophyll network in this giant antenna system is functionally even more tightly coupled to the core of PSI than the chlorophyll network in the plant PSI–LHCI complex.

Summary

PSI is a large membrane protein complex, present in plants, algae, and cyanobacteria. In cyanobacteria, it forms a trimer, where each monomer consists of 12 proteins and 127 cofactors. PSI catalyzes the light-induced electron transfer across the photosynthetic membrane from plastocyanin or cytochrome c_6 to ferredoxin or flavodoxin by a chain of electron carriers, consisting of six chlorophylls, two phylloquinones, and three 4Fe4S clusters. PSI contains a tightly coupled core-antenna system of 90 chlorophylls and 22 carotenoids, which is highly

conserved between plants and cyanobacteria and transfers the excitation energy to the core of PSI. In higher plants, a monomer of PSI forms a complex with four light harvesting proteins, while in cyanobacteria either membrane extrinsic phycobilisomes or (under iron deficiency) rings of the IsiA protein further increase the absorption cross section of PSI.

Glossary

D1 protein turnover Replacement of a nonfunctional D1 protein in the photosystem II (PSII) complex.

Photoinactivation Light-induced inactivation of the PSII electron transfer and water splitting.

PSII (photoinhibition) repair cycle Cycling of the PSII complexes between the grana- and stroma-exposed thylakoid membranes during the turnover of the D1 protein.

Biogenesis and Assembly of a New PSII Complex

Cooperation between Chloroplast and Nucleus

The PSII complex of eukaryotic organisms contains both nuclear and chloroplast-encoded gene products, as is the case with other photosynthetic protein complexes in the thylakoid membrane. This indicates that a tight cooperation exists between the organelle and nucleus in building up the PSII complex. From at least 25 genes encoding the PSII proteins, 15 genes reside in the chloroplast genome, rest of them locating in the nucleus.

Targeting the chloroplast-encoded PSII proteins

The majority of the PSII core proteins are chloroplast encoded. These comprise the D1, D2, CP43, CP47, cyt *b559 α* , and cyt *b559 β* proteins encoded by the *psbA*, *psbD*, *psbC*, *psbB*, *psbE*, and *psbF* genes, respectively. In addition, the PSII core proteins include the *psbH*, *psbI*, *psbJ*, *psbK*, *psbL*, *psbM*, *psbN*, *psbTc*, and *psbZ* gene products of low molecular weight (LMW). Translation of the chloroplast-encoded PSII core proteins takes place on the surface of the thylakoid membrane. Initiation of translation of many chloroplast-encoded proteins is regulated by nuclear-encoded messenger RNA (mRNA)-binding proteins. To what extent these proteins are involved in targeting the ribosome–mRNA complexes to the thylakoid membrane is, however, unclear. Insertion of the chloroplast-encoded PSII proteins to the thylakoid membrane occurs both co- and post-translationally, and several soluble and membrane proteins are involved in assisting these processes. Cotranslational membrane insertion is typical for the PSII core proteins with several transmembrane helices, such as the D1, D2, CP43, and CP47 proteins.

Targeting the nuclear-encoded PSII proteins

The nuclear-encoded PSII core monomer proteins are three LMW subunits, namely the *psbW*, *psbX*, and *psbTn* gene products. In addition, proteins of the light-harvesting chlorophyll *a/b*-binding protein complex II (LHCII) and the oxygen-evolving complex (OEC), composed of the gene products of *psbO*, *psbP*, *psbQ*, and *psbR*, are nuclear encoded. All the nuclear-encoded proteins are synthesized as precursors on cytosolic ribosomes. These precursors are subsequently targeted to the chloroplast via an N-terminal transit peptide, which is proteolytically cleaved after import into the chloroplast. The nuclear-encoded

precursor proteins targeted to the thylakoid lumen contain a bipartite N-terminal transit peptide, the last part of which is removed after the arrival of the transported protein into the lumen. The luminal proteins, including those for the OEC, use both the Sec machinery and the aminoglycoside-modifying enzyme (Δ pH) pathway in their insertion and translocation to the luminal side of the thylakoid membrane.

Assembly of a New PSII Complex

General features

During the past decade, significant progress has been made in elucidating the PSII assembly and turnover processes. Besides purely biochemical approaches, the assembly of PSII has been studied using plant and cyanobacterial mutants. Particularly useful have been the mutants deficient in a specific PSII subunit or carrying a mutation in a nuclear gene that affects the expression or assembly of a structural PSII subunit. In addition, studies on plastid development from etioplast to chloroplast have contributed to the understanding of PSII assembly. Furthermore, research on the light-induced turnover of the PSII complex has produced information that can be applied also for the research on the assembly process of a new PSII center.

Sequence of the assembly of PSII core, OEC, and LHCII proteins

Light is required for maturation of etioplasts to chloroplasts and for synthesis and assembly of most of the PSII subunits. However, some of the PSII subunits do not need light for synthesis, since they exist already in etioplasts. This is the case particularly with cyt *b559* and the OEC proteins. In the assembly of the PSII core proteins, the two-subunit cyt *b559* functions as the first assembly partner for the D2 protein. All these together form an initial complex that functions as a receptor for the cotranslational assembly of the precursor-D1 protein. The assembly process then continues by association of the *psbI* gene product and the CP47 protein to the PSII subcomplex. Subsequently, the *psbH* gene product, the CP43 protein, and several LMW subunits attach to the growing PSII subcomplex. Assembly of the additional LMW subunits, namely the *psbJ* and *psbL* gene products, is essential for subsequent proper association of the OEC proteins on the luminal side of the PSII core monomer. Finally, the rest of the LMW subunits, such as the

psbK, *psbW*, and *psbZ* gene products, are required for the last events of the assembly process. These events include dimerization of the PSII core monomer and the attachment of LHCII to the PSII complex, resulting in the formation of a PSII supercomplex. An array of such PSII supercomplexes exists in the grana membranes of chloroplasts.

Regulation of the PSII Assembly

Light is required for an efficient translation elongation and accumulation of the D1 protein as well as for synthesis of the CP43 and CP47 core proteins. In addition to light, regulation of synthesis and assembly of the PSII complex involves the availability of a variety of factors, including the ligation of pigments and cofactors (chlorophyll *a*, pheophytin, β -carotene, Fe, Mn, and plastoquinone) and the availability of the assembly partners.

The chloroplast-encoded core proteins, D1, D2, CP43, and CP47, are cotranslationally inserted into the thylakoid membrane. Pigments are thought to bind to these proteins during their cotranslational membrane insertion and concomitant association with assembly partner(s). Light is needed for chlorophyll biosynthesis at the level of conversion of protochlorophyllide to chlorophyll *a* but we lack the information on details of pigment binding, even though the importance of this event as a regulative step in the assembly of PSII has been known for a long time. It is clear, however, that the chlorophyll-binding proteins of PSII are stabilized by ligation of pigments. Most chlorophyll-binding proteins do not accumulate at all in a nonpigmented form.

Successful synthesis of the PSII core proteins requires the availability of assembly partners. Synthesis of the D2 protein is dependent on the presence of *cyt b559*. Furthermore, *cyt b559*/D2 subcomplex is indispensable for the synthesis of D1, and the *cyt b559*/D2/D1 subcomplex, in turn, functions as an assembly partner for CP47. From the PSII core proteins, CP43 seems to be synthesized quite independently.

Moreover, dozens of nuclear-encoded auxiliary protein are required for correct and efficient assembly of PSII. During the D1 protein translation and insertion into the membrane, the stromal proteins LPA1 and HCF136 as well as the luminal immunophilin CYP38 guide the proper folding of the D1 protein. On the other hand, LPA2 is responsible for the assembly of CP43 into PSII. The thylakoid lumen proteins are of utmost importance during the assembly of the PSII core complex and OEC proteins. These proteins include several luminal peptidyl-prolyl isomerases, OEC protein isoforms, and PSB27. Integration of the LHCII protein to the membrane is dependent on the presence of the thylakoid membrane protein ALB3.

Turnover of the D1 Protein of PSII

PSII Photoinactivation and the D1 Protein Damage

The PSII complex performs a remarkable task in splitting water molecules to oxygen and protons. Such oxidizing electron transfer reactions of PSII readily lead to the formation of highly reactive radicals that are potentially harmful to the protein moiety. Thus, PSII, when performing its normal function, is hazardous for itself.

The rate of PSII photoinactivation increases almost linearly with increasing light intensity. Under low light, the rate of photoinactivation is also low. The rate of inactivation correlates with the amount of photons absorbed and mediated to the reaction center. Upon inactivation, the PSII complex becomes unable to transfer electrons and split water molecules. A constant repair of inactivated complexes is required to guarantee the maintenance of a sufficient level of active PSII complexes for photosynthesis. The efficiency of repair is affected negatively by environmental stress factors, such as high light and the extremes of temperature. If the repair process cannot keep up with the rate of photodamage, nonfunctional PSII complexes start to accumulate. This situation leads to a measurable decrease in the rate of total photosynthesis.

The primary target of the photo-induced PSII damage is the reaction center protein D1. This fact reflects the grand design of PSII: only one protein of the multisubunit complex is primarily destroyed, whereas the rest of the proteins are rescued and used for reparation of the PSII complex. The primary photodamage is thought to include a conformational change and an oxidative damage to the D1 protein. These events, in turn, trigger the reaction center protein D1 to a substrate for proteolytic degradation. However, the actual nature of the primary photodamage is not yet properly understood.

PSII Photoinhibition Repair Cycle

Start of the repair process

Active PSII centers exist as dimers in the thylakoid membranes of grana stacks (Figure 1). After a light-induced damage to PSII, the LHCII antenna dissociates and monomerization of PSII occurs. PSII monomers then migrate from the grana to the stroma-exposed thylakoid membranes where a contact with the components acting in degradation and synthesis of the D1 protein is feasible. OEC dissociates from PSII and a partial disassembly of the PSII core proteins takes place. The stages from photodamage to degradation of the D1 protein are regulated by phosphorylation–dephosphorylation events of the PSII core proteins.

Degradation of the D1 protein

Degradation of the light-damaged D1 protein is a proteolytic process that occurs in a well-coordinated manner on the stroma-exposed thylakoid membranes, leaving the closest partner, the D2 protein, most often intact. The D1 protein is an integral membrane protein with five transmembrane helices. Between helices, there are loops both on the stromal and luminal sides of the thylakoid membrane. The loops are the preferential sites of the primary cleavage of an integral membrane protein, in general. In the case of the D1 protein, the stromal DE-loop shows the most important contribution to proteolysis, while the role of luminal AB- and CD-loops seems to be less important. The primary proteolysis of D1 produces fragments that are further degraded by the secondary proteolysis. Apparently, several enzymes of the FtsH and Deg protease families in concert degrade the D1 protein, however, the FtsH proteases being in dominant role. FtsH proteases are metalloproteases and form a heterohexameric complex on the stromal side of the thylakoid membrane. Deg proteases, most of which

are located in the thylakoid lumen, are endopeptidases and form a homotrimeric complex.

Synthesis of the D1 protein

Synthesis of the D1 protein during the PSII repair cycle shares features with synthesis of the D1 protein in the assembly of a new PSII complex (see above). The D1 protein is encoded by the *psbA* gene residing in the chloroplast genome. The *psbA* mRNA-ribosome complex is targeted to the stroma-exposed thylakoid membrane, where elongation of the nascent D1 chain takes place. The nascent D1 chain is cotranslationally inserted into the thylakoid membrane, where the D2 protein and cyt *b559* act as the first association partners. Elongation and concomitant membrane insertion of the D1 protein are controlled by a variety of factors. Such factors include association of the nascent chain with a translocon and availability of the assembly partners and pigment molecules. Further regulation on D1 synthesis is provided by transthylakoid proton gradient, reactive oxygen

species, and other redox-active chloroplast components. When all the five transmembrane helices have been synthesized, the precursor D1 protein releases from the ribosome. The fifth transmembrane helix traverses the membrane, finally having its carboxyl terminus in the thylakoid lumen.

Posttranslational events of the D1 synthesis and reactivation of the PSII complex

Posttranslational events of the D1 protein synthesis include several steps. First, during maturation of the D1 protein, the luminal processing protease CtpA removes the extension of 9–16 amino acids from the carboxyl terminus of the precursor D1 protein. This cleavage is necessary for ligation of the manganese cluster and reassociation of the OEC to the PSII complex. Finally, the properly assembled PSII monomer migrates back to the grana membranes, where PSII core dimerization and full reactivation of the PSII complex take place. The final reactivation stage also includes an association of the LHCII

antenna proteins to the PSII dimer. These final stages in the grana thus accomplish the PSII photoinhibition repair cycle providing an active PSII dimer for photosynthesis.

Glossary

Light-harvesting system Proteins that bind chlorophyll, carotenoids, and phycobilins which absorb light and transfer excitation energy to the reaction center.

Oxidation The process of removing an electron to a chemical species.

Photosystem Pigment–protein complex containing a light-harvesting system and a reaction center.

Radical Reactive chemical species with an unpaired electron.

Reaction center Protein subunits of the photosystem that bind redox active cofactors which use excitation energy to bring about charge transfer across the membrane.

Reduction The process of donating an electron to a chemical species.

Photosystem II (PSII) is a multisubunit protein complex embedded in the thylakoid membranes of oxygenic photosynthetic organisms: plants, algae, diatoms, and cyanobacteria. By using chlorophyll and carotenoid molecules and several redox active cofactors, it captures and uses solar energy to split water into molecular oxygen and reducing equivalents:

To produce a dioxygen molecule, four photons ($h\nu$) are needed to provide the energy to oxidize two water molecules. The dioxygen released maintains our oxygenic atmosphere and provides an ozone layer which protects us from the damaging effects of ultraviolet (UV) radiation. The reducing equivalents, which exit PSII as plastoquinol, are ultimately used, with the aid of additional light energy absorbed by photosystem I (PSI), to convert atmospheric carbon dioxide to the organic molecules that make up virtually all the biomass on our planet.

Morphology

Thylakoid Membrane

In chloroplasts of plants and green algae, the thylakoids are highly folded membranes having stacked (grana) and unstacked (stromal) lamellae regions. PSII is located mainly in the stacked regions. In cyanobacteria, diatoms, and other types of algae, the thylakoids do not have a clear differentiation into stacked and unstacked regions and PSII is more evenly distributed along the plane of the membrane. In all cases the thylakoid membrane encloses an inner aqueous compartment known as the lumen while the outer compartment is either the stroma of the chloroplast or cytoplasm of cyanobacteria referred to as the stromal side below.

Reaction Center

Reaction center (RC) is that part of a photosystem, like PSII, where light energy is converted to electrochemical potential energy. It is composed of protein-bound redox active cofactors that facilitate charge separation across the membrane. PSII exists *in vivo* either as a monomeric or a dimeric RC core

complex where the structure of the latter has been determined by X-ray crystallography (Figure 1).

Light-Harvesting Complexes

These pigment–protein complexes capture light energy and transfer it to the RC. They are often composed of several hundred pigment molecules, the exact number being dependent on growth conditions and type of organism. Various pigments are used so as to fully utilize the solar spectrum and for PSII these are different types of chlorophylls, phycobilins, and carotenoids. Some light-harvesting complexes (LHCs) are contained within the thylakoid membrane (intrinsic) and some attach to the surface (extrinsic) of the membrane.

Redox Active Cofactors

P680

P680 is composed of chlorophyll *a* molecule which, after excitation by the absorption of light to form P680*, gives up an electron to an acceptor, converting it to P680^{•+}. This radical cation has a redox potential estimated to be ~1.2 V or more, which is required to oxidize water. Its oxidation causes a bleach in its absorption spectrum centered at 680 nm. P680 is located on the luminal side of the PSII RC. Recent work suggests that the excited state P680* is delocalized over four symmetrically related chlorophyll molecules (depicted as P_{D1}, P_{D2}, Chl_{D1}, and Chl_{D2} in Figure 2) and that upon oxidation the hole becomes localized on a single chlorophyll (P_{D1}).

Pheophytin *a*

Pheophytin *a* (Pheo_{D1}) is the primary electron acceptor of PSII located toward the stromal side of the RC. It receives an electron from P680* in a few picoseconds to form a radical pair P680^{•+} Pheo^{•-}. The reduction of Pheo_{D1} can be detected as an optical absorption decrease at 422 nm and its reduction potential is ~-600 mV. The symmetrically related Pheo_{D2} (Figure 2) is not normally involved in electron transfer.

Figure 1 Side view of the PSII dimer perpendicular to the membrane normal derived from X-ray crystallography. Helices are represented as cylinders with D1 in yellow, D2 in orange, CP47 in red, CP43 in green, Cyt b559 in wine red, PsbL, PsbM, and PsbT in medium blue, and PsbH, PsbI, PsbJ, PsbK, PsbX, PsbZ, and the putative PsbN in gray. The extrinsic proteins are PsbO in blue, PsbU in magenta, and PsbV in cyan. Chlorophylls of the D1/D2 reaction center are light green, pheophytins are blue, chlorophylls of the antenna complexes are dark green, β -carotenes are in orange, hemes are in red, nonheme Fe is red, and Q_A and Q_B are magenta. The oxygen-evolving center (OEC) is shown as the red (oxygen atoms), magenta (Mn ions), and cyan (Ca^{2+}) balls. From Ferreira K, Iverson T, Maghlaoui K, Barber J, and Iwata S (2004) Architecture of the photosynthetic oxygen-evolving centre. *Science* 303: 1831–1838, with permission from AAAS.

Figure 2 Cofactors involved in electron transfer visualized perpendicular to the internal pseudo-twofold axis. Coloring scheme is the same as Figure 1. The phytol tails of the chlorophylls and pheophytins have been removed for clarity. The side chains of Y_Z (D1-Tyr161) and D1-His190 are shown in yellow and Y_D (D2-Tyr160) and D2-His189 in orange. The four chlorophylls comprising P680 are in direct van der Waals contact, and other electron transfer distances are given in angstroms. The electron transfer pathway is indicated by arrows and distances are given in angstroms based on the 3.5-Å crystal structure. Excitation of the reaction center, via light absorption by chlorophylls (Chl) in the antenna, drives electron transfer from the cluster of four chlorophylls bound to the D1- and D2-proteins, to the pheophytin (Pheo) acceptor leading to the radical pair $P680^{*+} Pheo^{*-}$. The radical cation of P680 is localized on P_{D1} although the primary electron charge separation probably occurs from Chl_{D1} followed by hole migration, while the radical anion is located on $Pheo_{D1}$. The electron on $Pheo_{D1}^{*-}$ is rapidly donated to a firmly bound plastoquinone Q_A (shown in purple) and then transferred to a second plastoquinone Q_B (also shown in purple). This electron transfer is aided by the presence of a nonheme iron located midway between them. When the Q_B plastoquinone is fully reduced and protonated to plastoquinol (PQH_2), it diffuses from the Q_B -binding site into the lipid matrix of the membrane. On the electron donor side, $P680^{*+}$ is reduced by a redox active tyrosine (Tyr_Z) which then extracts electrons from the $Mn_4Ca^{2+}O_4$ -cluster that constitutes the oxygen-evolving center (OEC). These electron transfer processes occur mainly on the D1 side of the reaction center and the symmetrically related cofactors located on the D2 side (Chl_{D2} and $Pheo_{D2}$) are nonfunctional. Other cofactors shown, including the heme of cytochrome b559 (cyt b559 shown in red) and the β -carotene molecule (shown in brown), play a role in protecting PSII against photoinduced damage. From Ferreira K, Iverson T, Maghlaoui K, Barber J, and Iwata S (2004) Architecture of the photosynthetic oxygen-evolving centre. *Science* 303: 1831–1838, with permission from AAAS.

Q_A

Q_A is a bound plastoquinone (PQ) molecule which undergoes a single reduction by PheoD1 $^{*+}$ in ~ 200 ps, forming the charge transport state P680 $^{*+}$ Pheo Q_A^+ where the redox potential of the semi-plastoquinone (Q_A^-) is ~ -150 mV.

Q_B

Q_B is also a PQ which can accept two electrons successively from Q_A^- and together with two protons (H^+) from the stroma or cytoplasm to form plastoquinol (PQH $_2$). In this fully reduced form, PQH $_2$ is released from the Q_B -binding site of the PSII RC and diffuses into the lipid matrix of the thylakoid membrane until it is oxidized by the cytochrome b_6f complex. The reducing equivalents are further energized by a second light reaction which occurs in PSI so as to reach a redox potential sufficient to reduce carbon dioxide.

Tyrosines Y_Z and Y_D

Y_Z is a redox active tyrosine 161 of the D1 protein which reduces P680 $^{*+}$. In so doing, it loses a H^+ from its phenolic group to the nearby H-bonded histidine 190 of the D1 protein (see Figure 2) and the resulting species is a neutral tyrosine radical $Y_Z^\bullet$. Symmetrically related to Y_Z is Y_D tyrosine 160 of the D2 protein (see Figure 2). Although this tyrosine is also H-bonded to D2His189 and can be oxidized by P680, it is not directly involved in water oxidation.

Chl $_{D1}$ and Chl $_{D2}$

Chl $_{D1}$ and Chl $_{D2}$ are two peripheral chlorophyll a molecules which under some circumstances are oxidized by P680 $^{*+}$ and are located close to the A/B transmembrane helices of the D1 and D2 proteins, respectively. The relatively long distance from the P680 chlorophylls suggests that the electron transfer, which is in the millisecond timescale, is facilitated by β -carotene molecules, one of which is shown in Figure 2. The function of this redox activity seems to be to protect PSII against oxidative damage.

Hemes

There are two hemes in the PSII of cyanobacteria, the high potential cytochrome b559 and the low potential cytochrome c550. The former can be oxidized by P680 with the electron transfer being facilitated by a β -carotene molecule positioned midway between it and P680 (see Figure 2). This millisecond electron transfer, like that associated with Chl $_{D1}$ and Chl $_{D2}$, seems to play a protective function for PSII. The heme of cytochrome b559 is ligated by two histidines equally provided by the PsbE and PsbF proteins. In contrast, cytochrome c550 is not normally redox active, is located in the extrinsic PsbV protein, and is found only in PSII of cyanobacteria and red algae. Cytochrome b559 is conserved in PSII of all types of oxygenic photosynthetic organisms.

Mn $_4$ Ca $^{2+}$ -cluster

A cluster of four manganese atoms together with a Ca $^{2+}$ atom makes the catalytic center (Mn $_4$ Ca $^{2+}$ -cluster), where the oxidation of two substrate water molecules occurs. The removal of

4e and 4 H^+ requires four successive oxidations of P680, and there is evidence that $Y_Z^\bullet$ may act as an H^+ as well as an electron acceptor and therefore is directly involved in the water oxidation reaction.

The highest resolution X-ray crystallography (1.9 Å) has revealed that Mn $_4$ Ca-cluster is organized as a 'distorted chair', with an asymmetric cubane-like structure composed of three Mn atoms, one Ca $^{2+}$ ion, and four oxygen atoms in the corners of this structure. The fourth Mn (Mn4, or the dangler Mn) is located outside of the cubane and is linked to Mn1 and Mn3 of the cubane via two di- μ -oxo bridges involving the fifth oxo and a bridging oxo of the cubane. This general geometry of cubane has been suggested previously based on lower 3.5-Å resolution diffraction. Four water molecules are associated with the cluster, two ligated to Mn4 and the other two to the calcium ion. The remaining ligands are provided by the D1 and CP43 proteins.

Bicarbonate

A bicarbonate provides bidentate ligation to the nonheme iron with further histidine ligands provided equally by the D1 and D2 proteins. Although tentatively modeled into an earlier crystal structure of PSII as a ligand to the Mn $_4$ Ca $^{2+}$ -cluster, there is no further evidence to support this, even though there is some support for this anion playing a role in the water oxidation process.

Chloride

Two chloride ions are located in the vicinity of the Mn $_4$ Ca-cluster but not in ligating distance. One site is close to D2Lys317 and backbone nitrogens of D1Glu333 and the other close to CP43Glu354 and the backbone nitrogens of D1Asn338. They seem to play a role in maintaining the coordination environment of the metal cluster while at the same time facilitate the transport of water and protons to and from the catalytic site.

Proteins

The RC core complex of PSII is composed of a large number of intrinsic and extrinsic proteins encoded by *psb* genes (see Table 1). The RC core is serviced by LHC proteins, the number and type of which vary between different types of organisms. Plants and green algae have their LHC proteins encoded by *cab* genes while red algae and cyanobacteria contain phycobiliproteins encoded by *apc* and *cpc* genes. Here we confine ourselves to PSII RC core proteins encoded by the *psb* genes (Figure 3) but note that there are differences between plants and cyanobacteria.

PsbA-D1 Protein

After C-terminal posttranslational modification, this protein has a molecular mass of ~ 38 kDa and contains ~ 350 amino acids depending on species. It has five transmembrane α -helices (A–E), DE stromal surface α -helix, and CD lumenal surface α -helix. It binds the majority of the cofactors involved in PSII-mediated electron transport: Y_Z is Tyr161, P680 $^{*+}$ is chlorophyll a ligated by His198, called P $_{D1}$, Pheo $_{D1}$ is H-bonded by Tyr126 and Glu130, Q_B via interactions with

Table 1 Psb protein subunits of PSII RC core complex

Gene	Subunit	Mass (kDa)	No. of transmembrane α -helices
<i>psbA</i> (c)	D1	38.021 (S)	5
<i>psbB</i> (c)	CP47	56.278 (S)	6
<i>psbC</i> (c)	CP43	50.066 (S)	6
<i>psbD</i> (c)	D2	39.418 (S)	5
<i>psbE</i> (c)	α -cyt b559	9.255 (S)	1
<i>psbF</i> (c)	β -cyt b559	4.409 (S)	1
<i>psbH</i> (c)	H protein	7.697 (S)	1
<i>psbI</i> (c)	I protein	4.195 (S)	1
<i>psbJ</i> (c)	J protein	4.116 (P)	1
<i>psbK</i> (c)	K protein	4.283 (S)	1
<i>psbL</i> (c)	L protein	4.366 (S)	1
<i>psbM</i> (c)	M protein	3.755 (P)	1
<i>psbN</i> (c)	N protein	4.722 (T)	1

<i>psbP</i> (n)	23-kDa P protein	20.210 (S)	0
<i>psbQ</i> (n)	16-kDa Q protein	16.523 (S)	0
<i>psbR</i> (n)	R protein	10.236 (S)	0
<i>psbS</i> (n)	S protein	29.197 (S)	4
<i>psbT</i> (c)	T _C protein	3.849 (S)	1
<i>psbT</i> (n)	T _n protein	5.000 (A)	0
<i>psbU</i>	U protein	10.491 (Sy)	
<i>psbV</i>	V protein	15.121 (Sy)	0
<i>psbW</i> (n)	W protein	5.928 (S)	1
<i>psbX</i> (n)	X protein	4.225 (S)	1
<i>psbY</i> (c)	Y protein	4.202 (Sy)	1
<i>psbZ</i> (c)	Z protein	6.541 (S)	2
<i>ycf 12</i>	Ycf protein	4.143 (Sy)	1

These proteins are products of the *psbA* to *psbZ* plus *ycf 12* genes that occur in oxygenic organisms.

In eukaryotic organisms, the *psb* genes are located in either the chloroplast (c) or nuclear (n) genes.

The molecular masses of the mature PsbA–PsbZ/Ycf12 proteins are calculated from the protein sequences reported in the SwissProt database using the MacBioSpec program (Sciex Corp., Thornhill, ON, Canada) for spinach (S), pea (P), tobacco (T), *Arabidopsis* (A), and *Synechocystis* PCC6803 (Sy).

His 215 and Ser 264. The accessory Chl_{D1} is coordinated by a water ligand H-bonded to Thr179. Mn₄Ca²⁺-cluster is ligated by Asp170, Glu189, His332, Glu 333, Asp342, and Ala344. With the exception of Glu189 and His332, all other D1 protein ligands are bidentate carboxylate. The D1 protein also binds a nonheme iron, which is normally redox inactive and positioned between Q_A and Q_B, and is ligated by His215 and His272. The D1 protein also contributes to the binding of two chloride molecules near to the Mn₄Ca²⁺-cluster. Another important property of the D1 protein is that it turns over more rapidly than any other protein in the thylakoid membrane. This remarkable feature is linked to the fact that PSII is susceptible to photoinduced damage leading to photoinhibition and a lowering of photosynthetic efficiency. The degradation, synthesis, and reinsertion of this protein into the RC core complex represent a very important aspect of the dynamics of PSII.

PsbB-CP47

This highly conserved PSII RC protein consists of ~500 amino acids and has a molecular mass of ~56 kDa depending on

species. It is often known as CP47 and has six transmembrane α -helices (I–VI) arranged in a ring consisting of three pairs with N- and C-termini exposed at the stromal surface (Figure 3). The luminal loop joining transmembrane helices V and VI is large, consisting of 200 amino acids having two long and four short helices as well as three β -sheets. It binds 16 chlorophyll *a* molecules and five β -carotenes. Most of the Chls are ligated to His residues located in the transmembrane helices and form an LHC system for the RC. Where they are not, three water molecules act as ligands. The large luminal loop functions indirectly in the water oxidation reaction by interacting with the D2 protein which is adjacent to it. Depletion of the *psbB* gene and a wide range of site-directed mutational studies have emphasized the absolute requirement of the PsbB protein in PSII assembly and function.

PsbC-CP43

After posttranslational processing, the PsbC-CP43 protein, depending on species, contains ~470 amino acids and has a molecular mass of ~50 kDa. It is homologous with PsbB (CP47) in that it has six transmembrane α -helices arranged in the same way but located on the D1 side of the RC (see Figure 3). It also contains a considerable number of histidine residues which are involved in ligating some of the 13 Chl_a bound to this protein. Where they are not, CP43Asn39 and two water molecules act as ligands. Like CP47, CP43 binds three β -carotene molecules and has a large luminal loop joining helices V and VI, which is slightly smaller, having ~150 amino acids. It contains two long and three short helices one of which is a 3₁₀ helix consisting of the highly conserved GGETMRFW motif where E is Glu354 which provides a bidentate ligand to the Mn₄Ca-cluster and R is Arg357 which is within the second coordination sphere of the metal cluster. It also differs from CP47 in that in plants (but not in algae and cyanobacteria) its N-terminal threonine can be reversibly phosphorylated. Moreover, CP43 seems to be more weakly associated with PSII compared with that of CP47, a feature which may be important when the D1 protein is degraded and replaced. Despite these differences, CP43, like CP47, acts as an LHC for PSII and its presence is also necessary for water splitting activity since it provides amino acids which are intimate with the catalytic center.

PsbD-D2 Protein

The PsbD-D2 protein is homologous to the D1 protein. Although it is slightly larger than the D1 protein, having in the region of 353 amino acids and a molecular mass of ~39.5 kDa, depending on species it has five transmembrane helical segments organized in the same way as the D1 protein (see Figure 3). Compared with the D1 protein it is involved to a lesser extent in binding active cofactors. There are two chlorophylls P_{D2} and Chl_{D2} which together with P_{D1} and P_{D1} form the cluster constituting P680* and are ligated to His197 and a water molecule, respectively. The binding of Q_A involves at least His214, Phe261, and possibly Trp253 and Leu267. The D2 protein also provides ligands for the nonheme iron being His214 and His268. Normally the D2 protein does not turn over rapidly like the D1 protein but, under extreme conditions (e.g., irradiation with damaging UV light), it will be replaced by a repair process.

Figure 3 View of the PSII monomer along the membrane normal from the luminal side showing the positioning and transmembrane helices of the intrinsic protein subunits. They are related to same proteins in the other monomer by the twofold axis shown as a dotted line and running along the monomer/monomer interface. The pseudo-twofold axis perpendicular to the membrane plane passing through the nonheme Fe relates the transmembrane helices of the D1/D2 heterodimer, the low molecular subunits, PsbI and PsbX and CP43 and CP47 as emphasized by the black lines encircling these subunits. Coloring is the same as in Figure 1. From Ferreira K, Iverson T, Maghlaoui K, Barber J, and Iwata S (2004) Architecture of the photosynthetic oxygen-evolving centre. *Science* 303: 1831–1838, with permission from AAAS.

PsbE and PsbF

These are the α - and β -subunits respectively of cytochrome b559. After processing, the PsbE and PsbF contain 82 and 38 amino acids in most higher plants, and have molecular masses of ~ 9.3 – 4.4 kDa. Both subunits have a single transmembrane helix with their N-termini exposed to the stromal surface.

The α -subunit is characterized by having a long C-terminus of ~ 44 amino acid residues extending from the luminal surface of the membrane, while the β -subunit has essentially no luminal domain. Of considerable importance is that each subunit contains a conserved histidine residue which is located within the membrane-spanning region toward the stromal surface. These two residues form axial ligands to the heme of the cytochrome. Although it had been argued by some that there are two cyt b559 per RC, all X-ray crystal structures find only one. This cytochrome is located on the D2 side of the RC (see Figure 3). The deletion of the *psbE* gene results in a lack of assembly of PSII. On the other hand, replacement of the His residue in the α -subunit can lead to an assembled and functionally active PSII complex even when no heme is ligated to the PsbE and PsbF proteins. Normally the heme has a high redox potential of ~ 0.4 V but, under some circumstances, this potential is lowered to 0.15 V or less. The chemical basis of this redox shift and its significance, if any, are unclear. Under some circumstances, usually when the water splitting reaction is inhibited such as at low temperature, the heme of cyt b559 is oxidized by $P680^{+\bullet}$. Recent structural models show the heme to be at least $40 \text{ \AA}$ from P680, which is too far to account for

the millisecond time constant for its oxidation. Accordingly, it has been suggested that a β -carotene molecule associated with the D2 protein acts as a redox intermediate between the cyt b559 and $P680^{+\bullet}$. The reduction of the oxidized heme may involve Q_A^- , Q_B^- , or $\text{Pheo}^{\bullet-}$ but again there is a distance problem, with the required electron donation occurring over distances of $28 \text{ \AA}$ or more, according to the recent X-ray structures. It seems likely that cyt b559 plays a protective role in minimizing photodamage of the RC.

PsbG

A chloroplast gene was initially called *psbG* but it was shown later that the product of this gene was not a PSII protein but rather a component of a chloroplast-located nicotinamide adenine dinucleotide phosphate (NADPH)/quinone oxidoreductase. This gene is now known as *ndhK*.

PsbH (H-Protein)

In higher plants, the PsbH protein contains 72 amino acids and has a calculated mass of ~ 7.7 kDa. In cyanobacteria the protein is slightly smaller (~ 6.5 kDa) with a truncated N-terminus and as such does not have the N-terminal threonine residue which is conserved in all higher plant and green algal sequences which is the site for reversible phosphorylation. The functional significance of the phosphorylation process is unclear. The higher plant the PsbH protein is

characterized by having a single transmembrane helix with a long N-terminal region consisting of ~41 amino acids at the stromal surface, which reduces to ~30 residues in the case of cyanobacteria. It is located adjacent to the PsbX protein on the D2/CP47 side of the RC (see Figure 3). The *psbH* gene can be deleted from the cyanobacterium *Synechocystis* without impairing the assembly of PSII and photoautotrophic growth. The knockout mutant was, however, more sensitive to photoinhibition than the wild type. This sensitivity seemed to be due to the partial inhibition of the D1 protein repair process rather than to an increase in photochemical damage. In contrast, when the *psbH* gene was deleted in *Chlamydomonas reinhardtii*, PSII did not assemble.

PsbI (I-Protein)

The PsbI protein has a molecular mass of ~4.2 kDa. In most eukaryotes, this protein contains 35 amino acids and is predicted to have a single transmembrane helix with a short N-terminal region at its stromal end. It is located close to the D1/D2 heterodimer, being adjacent to the β -helix of the D1 protein (see Figure 3). Its position is related to the PsbX protein by the same pseudo-twofold axis which relates the transmembrane helices of the D1 and D2 proteins. Interestingly, the mature protein retains the initiating N-formyl group at its N-terminal methionine residue. The *psbI* gene has been deleted in the green alga *Chlamydomonas* and the cyanobacterium *Synechocystis*, without inhibiting PSII assembly and photoautotrophic growth. Thus, the function of the PsbI protein remains unknown.

PsbJ (J-Protein)

In most organisms, the *psbJ* gene is located in a gene cluster also containing the *psbE*, *psbF*, and *psbL* genes. The PsbJ protein is highly conserved, consists of 39 amino acids, and has a calculated molecular mass of 4.1 kDa. It has one transmembrane helix and located adjacent to the PsbE/F proteins of Cyt b559 (see Figure 3) and forms a channel for Q/PQH₂ diffusion in and out of PSII. The *psbJ* gene has been deleted in cyanobacteria to generate a knockout mutant which assembles PSII at a lower level than the wild type and has an impaired rate of Q_A to Q_B electron transfer. Nevertheless, they can grow photoautotrophically but at a rate slower than WT.

PsbK (K-Protein)

This ~43-kDa protein is highly conserved and has 37 amino acid residues. It has a single transmembrane helix with a kink due to the presence of a proline. Of particular note is that in higher plants, 24 amino acids are posttranslationally cleaved from the initial gene product. In cyanobacteria, eight amino acids are removed after translation. These pre-sequences probably bring about the insertion of the protein into the thylakoid membrane such that its N-terminus is on the luminal side. PsbK is located on the outer surface of the PSII RC core, close to helices I and II of CP43 and clustered with the PsbZ and Ycf12 proteins (see Figure 3). Deletion of the *psbK* gene in cyanobacteria has very little effect on photoautotrophic growth and PSII activity. In the case of green algae, however, the deletion of the

gene destabilized the PSII complex and the transformant was unable to grow photoautotrophically.

PsbL (L-Protein)

This highly conserved PSII protein contains 37 amino acids and has a calculated molecular mass of ~4.4 kDa. In most organisms, its gene is located in the cluster together with *psbE*, *psbF*, and *psbJ*. It consists of a single transmembrane helix and is located, together with PsbM and PsbTc, at the monomer-monomer interface of the dimeric core complex (see Figure 3). Inactivation of the *psbL* gene in cyanobacteria results in a loss of PSII-mediated oxygen evolution and the transformant is unable to grow photoautotrophically. It has also been reported that PsbL is required for normal functioning of the Q_A site based on studies with isolated PSII complexes. This conclusion was reinforced by the finding that PsbL is required for the oxidation of Y_Z by P680^{•+}. As a consequence, the primary quinone acceptor is destabilized by the increased probability of rapid recombination between Q_A⁻ and P680^{•+}.

PsbM (M-Protein)

The PsbM protein has one transmembrane helix with a very short N-terminal extension on the stromal side. It contains 33 amino acids and has a molecular mass of ~3.7 kDa. It is located with PsbL and PsbTc at the monomer-monomer interface of the dimeric core complex (see Figure 3). However, deletion of the *psbM* gene in cyanobacteria is not sufficient to prevent dimer formation which only occurs when *psbTc* is also deleted.

PsbN (N-Protein)

This protein is predicted to be in both cyanobacterial and plant PSII. However, it has not been detected directly in plant PSII and it is not present in the crystal structure of PSII isolated from cyanobacteria. PsbN has a predicted single transmembrane helix. Deletion of both *psbN* and *psbH* genes from cyanobacterium *Synechocystis* caused no effect other than those observed in the absence of *psbH* alone. Thus, the function and location of *psbN* are unknown.

PsbO (O-Protein)

PsbO is often called the 'manganese-stabilizing' protein. Between higher plants and cyanobacteria this protein is highly conserved containing, after processing, 241–247 residues. Although the mature PsbO protein is often referred to as the 33-kDa protein, its calculated molecular mass is ~26.5 kDa. It is an extrinsic protein having as its main body a β -barrel composed of eight antiparallel β -strands. A very large loop joining β -strands 1 and 2 provides a head domain which binds to the luminal surfaces of the D1, D2, CP43, and CP47 proteins (see Figure 1). The β -barrel is not hollow but full of bulky side chains. It plays an important role in stabilizing the Mn₄Ca-cluster and maintaining an optimal environment for water oxidation to occur. Various studies indicate that it does so by controlling Ca²⁺ and Cl⁻ levels at the catalytic site, but it does not bind Mn directly. The deletion of the *psbO* gene in

cyanobacteria does not prevent water oxidation unless the *psbV* gene is also deleted while the equivalent single *psbO* deletion in green alga inhibits the assembly of a functional PSII core complex.

PsbP (P-Protein)

PsbP is a 23-kDa extrinsic protein. After processing, this protein consists of ~186 amino acids with a calculated molecular mass of ~20 kDa. It consists mainly of β -sheets. Although it is a well-established component in PSII of higher plants and green algae, its presence in cyanobacteria is not stoichiometric with PSII and not present in the crystal structures. Like PsbO, its function seems to be to optimize the Ca^{2+} and Cl^- levels needed for the water oxidizing reaction and is located in the vicinity of this 33-kDa protein to which it binds.

PsbQ (Q-Protein)

The PsbQ mature protein contains ~49 amino acids and, like PsbP, is located close to the 33-kDa protein and the Mn_4 -cluster. Its core consists of a four helical bundle. Like PsbO and PsbP, it seems to be involved in optimizing the ionic environment necessary for oxygen evolution. PsbQ, however, is not found in the crystal structure of cyanobacterial PSII, although a *psbQ*-like gene is present and the protein has been detected in PSII preparation at stoichiometric levels. Its binding to PSII requires the presence of PsbO and PsbP.

PsbR (R-Protein)

The role of PsbR is unknown. It has a molecular mass of 10.2 kDa and consists of ~99 amino acids. It seems to be an extrinsic protein of plant PSII, and is bound relatively tightly to the luminal surface in the vicinity of the water splitting site. Whether it has a transmembrane helix is a matter for debate. It does not exist in cyanobacteria.

PsbS (S-Protein)

The PsbS protein consists of ~205 amino acids and has an apparent molecular mass of 22 kDa, although its calculated mass is ~29 kDa. It is predicted to have four transmembrane helices. Helices I and III, and II and IV, are homologous indicating that the protein is derived from internal gene duplication. Sequence homology studies suggest that PsbS is related to Chla/Chlb-binding antenna Lhcb1–6 proteins (*cab* gene products) and is likely to be a chlorophyll-binding protein. A functional role for PsbS, therefore, could be to act as a pigment chaperonin which aids the incorporation of chlorophyll molecules into the various pigment-binding proteins of PSII. This protein has also been implicated in the protection of PSII against photoinduced damage (photoinhibition). It does not exist in cyanobacteria.

PsbT_C (T_C-Protein)

The chloroplast-encoded PsbT_C protein is also found in cyanobacteria. It contains 30–34 amino acids, has a molecular weight of ~3.9 kDa, and retains the initiating *N*-formyl group

on its N-terminal methionine residue. It has a single transmembrane helix which is located in the N-terminus of the protein. The *psbT_C* gene was formerly known as *ycf8* and is located close to the *psbB* gene in the chloroplast genome. The first identification of this subunit was made by comparing wild type and a mutant of *Chlamydomonas* that lacked the *psbT_C* gene. This work also showed that the PsbT_C is a PSII protein and is required for optimal activity under high-light conditions so as to prevent photoinhibition. It is located with PsbM and PsbL in the dimerization domain (see Figure 3), and the deletion of its gene together with that of PsbM results in monomerization of the dimeric PSII core.

PsbT_N (PsbT_N-Protein)

The PsbT_N is a nuclear-encoded hydrophilic 5-kDa protein which copurifies with PsbO. Although its function is unknown, it seems to be an extrinsic protein located on the luminal surface of PSII. The mature PsbT_N protein consists of ~28 amino acids in higher plants and the presence of two cysteine residues suggests that it contains a disulfide bridge. It is not present in cyanobacteria.

PsbU (U-Protein)

This is a cyanobacterial all α -protein extrinsically located on the luminal surface of PSII close to the 33-kDa protein (see Figure 1). It has an apparent molecular mass of ~11 kDa and binds no cofactors. It is also found in red algae but not in plants and green algae.

PsbV (V-Protein)

PsbV is a heme-containing protein known as cytochrome c550 and is found only in cyanobacteria and red algae. It has a molecular mass of 15 kDa and is an extrinsic protein found on the luminal surface of PSII close to PsbO and PsbU (see Figure 3). It plays no direct role in water oxidation, although it does help to provide a $\text{Ca}^{2+}/\text{Cl}^-$ environment at the catalytic site. It does not, however, bind directly to PsbO but indirectly via PsbU, which forms a bridge.

PsbW (W-Protein)

The PsbW protein is found in PSII cores isolated from higher plants and green algae. A cyanobacterial PsbW-like gene has also been documented which has a low homology with the eukaryotic equivalent, and therefore there is some uncertainty whether or not cyanobacteria contain the PsbW. In any event, it is not present in the cyanobacterial PSII crystal structures. In higher plants and green algae, it is nuclear-encoded and is processed to a mature protein having an apparent molecular mass of 6.1 kDa and consists of 54–56 amino acids. It is predicted to have one membrane-spanning region with its N-terminus located on the luminal side of the membrane. This orientation is consistent with the pre-sequence of the PsbW protein having characteristics of a target sequence typical for luminal proteins. The function of PsbW is unknown.

PsbX (X-Protein)

The PsbX protein is nuclear-encoded in higher plants and green algae, and consists of ~42 amino acids. In higher plants, its synthesis is tightly regulated by light. The mature PsbX protein has a molecular mass of ~4.1 kDa and a single transmembrane helix having its N-terminus in the lumen. It has been detected in the oxygen-evolving PSII core complex of higher plants and cyanobacteria. In the latter, it is located close to the D1/D2 heterodimer and close to PsbH, being adjacent to the B-helix of the D2 protein. Its position is related to the PsbI protein by the same pseudotwofold axis which relates the transmembrane helices of the D1 and D2 (see [Figure 3](#)). The deletion of the *psbX* gene in cyanobacteria did not inhibit PSII assembly and photoautotrophic growth. However, these studies suggest that PsbX may play a role in the electron transfer functions of Q_A and Q_B .

PsbY (Y-Protein)

This protein is located in PSII of plants, algae, and cyanobacteria. It has a molecular mass of ~4.2 kDa, consists of 36–39 amino acid residues, and has one transmembrane segment. The deletion of the *psbY* gene in cyanobacteria does not impair the water oxidation process, probably because of its peripheral location which is close to PsbE (see [Figure 3](#)). The function of this subunit is unclear and was only detected in one of the crystal structures of cyanobacterial PSII.

PsbZ

This 6.8-kDa protein contains 62 amino acids and forms two transmembrane helices. It is located at the peripheral edge of the PSII complex adjacent to PsbC (CP43) where it clusters with the Psb K, PsbJ, and Ycf12 proteins (see [Figure 3](#)). This cluster probably functions to stabilize the binding of pigments, particularly β -carotene.

Ycf12 (Also Called Psb30)

Subunit Ycf12 is situated next to the PsbK, PsbJ, and PsbZ proteins (see [Figure 3](#)), having a single transmembrane helix with its N-terminus in the lumen. It directly interacts with PsbK and PsbZ and coordinates a Ca^{2+} ion. A cyanobacterial mutant with the *ycf12* gene deleted possesses oxygen-evolving activity comparable with wild type at normal light intensities.

Conclusion

Here, 27 different Psb protein subunits have been described that are found in the PSII RC core (20 intrinsic and seven extrinsic). In a few cases, the subunits are specific either to plants and green algae or to red algae and cyanobacteria. In addition, there may be some other candidates which have yet to be characterized in detail including some like Ycf48, Psb27, and Psb29 which seem to be involved in PSII assembly and maintenance. Although the X-ray structures of the cyanobacterial PSII RC core have unambiguously assigned all proteins in the electron density maps, none of these proposed assembly proteins are present. In addition to protein assignments, the most recent X-ray structures of the cyanobacterial PSII RC core have also identified, per monomer, the positions of 35 chlorophylls, 11 all-*trans* β -carotenes, at least 20 lipids (six monogalactosyldiacylglycerols (MGDGs), five digalactosyldiacylglycerols (DGDGs), four sulfoquinovosyldiacylglycerols (SQDGs) and five phosphatidylglycerols (PGs)), 15 detergent molecules, and more than 1300 water molecules of which almost all are located in the two layers located on the stromal and luminal sides.

Glossary

Chlorophyll excited state State that is formed after absorption by a chlorophyll molecule of a light quantum. At the molecular orbital level, it corresponds to the hopping of an electron from the highest occupied molecular orbital to the lowest unoccupied molecular orbital.

Oxidation De-electronation reaction or abstraction of an electron from a molecule.

Reduction Electronation reaction. An electron transfer reaction occurs between an electron donor

(which is oxidized) and an electron acceptor (which is reduced). In the case of photosynthetic water oxidation, two molecules of water (H_2O) are oxidized into molecular oxygen and serve as an electron source.

S_i states Successive states, as defined by B Kok, formed during the accumulation in the catalytic center of the water-splitting enzyme of the oxidizing power required to split water into dioxygen. The transition from state S_i to state S_{i+1} reflects the abstraction of one electron from the catalytic center.

Photosystem II and the Water-Splitting Enzyme

The Photosystem II Complex

Water oxidation into dioxygen (O_2) follows the equation

where H^+ and e^- stand for protons and electrons, respectively. Water is obviously a very stable compound and its oxidation requires the availability of strongly oxidizing species (at pH 7.0 the midpoint potential of the $\text{H}_2\text{O}/\text{O}_2$ couple is 810 mV). This oxidizing power is formed at the expense of light absorption and the conversion of light energy into electrochemical energy. The action spectrum of oxygen emission showed that it is sensitized by pigments associated with photosystem II (PS II). Photosystem II is a large pigment protein complex located in the thylakoid membrane of the chloroplast, in green algae or higher plants or in the cytoplasmic membrane in cyanobacteria. As illustrated in [Figure 1](#), the core of PS II is composed of two homologous polypeptides (D_1 and D_2 , D for diffuse electrophoretic profile), each of which consists of five transmembrane helices. It bears various redox cofactors, including a chlorophyll dimer ($\text{P}_\text{A}\text{P}_\text{B}$), two chlorophyll monomers (B_A and B_B), two pheophytins (Ph_A and Ph_B), and two quinones Q_A and Q_B . Among the various photosynthetic reaction centers, PS II is unique because it bears a tetra-manganese cluster which, coupled to a redox active tyrosine Y_Z , is responsible for water splitting into oxygen. The core of the reaction center is surrounded by pigment (chlorophyll and carotenoid)-binding proteins, which increase by a factor of ≈ 200 its absorption cross section. Thus, under normal solar radiance, one photon is absorbed by PSII every ≈ 5 ms. The absorption of a photon by one of the chlorophyll borne by the pigment-binding proteins results in the formation of an excited state of a chlorophyll, that is, an electron jumps from the highest occupied molecular orbital to the lowest unoccupied orbital of higher energy. Provided other pigments are close enough, this excitation energy may hop from one pigment to another and then be funneled to the core of the reaction center and

more precisely to the primary donor B_A (denoted B_A^* in the excited state). The singularity of B_A resides in the fact that in its close vicinity one finds an electron acceptor (Ph_A). The excitation energy, by weakening the binding energy of the electron by the energy of the transition between the two molecular orbitals, allows the electron transfer reaction between B_A^* and this nearby acceptor to occur, yielding the charge-separated state ($\text{B}_\text{A}^+\text{Ph}_\text{A}^-$). This state is then further stabilized by successive electron transfer steps between the different redox compounds. At room temperature, the first oxidized cofactor is essentially P_A . It is reduced in a few tens of nanoseconds by the redox active Y_Z (Y161 of the D_1 polypeptide), which is, in turn, reduced at the expense of the water-splitting enzyme. As shown in [Figure 1](#), despite the arrangement of the various redox cofactors in two symmetrical branches with respect to a pseudo C_2 symmetry axis perpendicular to the membrane plane, electron transfer only proceeds down one of these two branches indicating that function does not strictly follow structure.

The Water-Splitting Enzyme

As just described, conversion of light energy into electrochemical energy is a one-electron process. However, water oxidation into dioxygen is a four-electron process. Taking advantage of the possibility to trigger the light-induced electron-transfer reaction by short light flashes, P. Joliot showed that the oxygen emission yield is maximum after the third, seventh, eleventh... flash of a series ([Figure 2](#)). This oscillating pattern with a periodicity of four was modeled by B. Kok who postulated, on this basis, the existence of a charge-storing device allowing, in a single catalytic unit associated with PSII, the accumulation of the four oxidizing equivalents needed to split water into oxygen. In this model, illustrated in [Figure 2](#), the catalytic center has five different oxidation states (S_0 , S_1 , S_2 , S_3 , and S_4). Four successive light-induced oxidation triggers the four successive transitions between the S_i and S_{i+1} states. Upon S_4 formation, oxygen is produced and released while S_0 is

regenerated. The beauty of the Kok model resides in its ability to fully describe the function of the enzyme without any assumption neither on the chemical nature of the transient states it involves nor on the precise mechanism underlain by the successive transition between the S states. This accounts for its success as a working model ever since it was enounced. Simultaneous to the discovery of this charge-storing device, G. Cheniae and co-workers evidenced the requirement for manganese atoms in water splitting. The determination of a stoichiometry of four Mn atoms per PSII complexes provided the chemical basis for the catalytic center where the accumulation of the oxidizing equivalent produced by light-induced charge separation occurs. Together with this manganese cluster, the catalytic center bears two ions, Ca²⁺ and Cl[−]. In the absence of either one of these two ions, the lower S states (S₀ and S₁) may undergo oxidation but the advancement of the Kok cycle cannot be completed and water splitting is inhibited. The water-splitting enzyme further comprises extrinsic polypeptides (Figure 1(a)), which stabilizes the assembled tetranuclear cluster.

The Assembly of the Manganese Cluster

The ligands involved in the Mn₄Ca cluster binding to the protein backbone are provided by the polypeptides D₁ and CP43 (Figure 1(b)). The assembly of the Mn cluster requires Mn^{II}, in the Mn(OH)⁺ or Mn(OH)₂ form, Ca²⁺, Cl[−], and light. The absorption of light by PSII produces the oxidant Y_z^{ox}, which oxidizes the Mn^{II} ions. The first oxidation of a Mn^{II} has a high quantum yield, unlike the following steps which are needed for the oxidation-induced association of the stable tetra nuclear cluster.

The Thermodynamic and Kinetic Features of the Water-Splitting Enzyme

Before attempting to address the mechanism of water oxidation, one should question the thermodynamic and kinetic issues of this reaction. Obviously, water is a very stable molecule under physiological conditions, while its oxidation into

Figure 2 (Top) The O_2 emission yield as a function of the flash number in a series. Note that this yield depends on the flash number with a periodicity of four. (Bottom) The charge-storing device allowing accumulation of the oxidizing power needed to split water as modeled by Kok.

molecular oxygen is likely to involve the transient formation of highly reactive species such as oxo-radicals, hydrogen peroxides, etc. The enzyme must meet the following requirements: accumulate enough oxidizing power to not only perform a very demanding reaction with respect to common biological redox potential but also prevent side reactions, which are thermodynamically made possible by the accumulation, in a single catalytic site, of such an oxidative power.

The Redox Potential of the Different S States

Until now, the redox potentials of the different S states have not been determined by direct redox titration. They could only be inferred from the redox potentials of other cofactors found in the PS II reaction centers combined with the free-energy change associated with the electron transfer reaction between the S states and these cofactors. There are thus large error bars on the value, which can be found in the literature. The redox potential of the P^+/P couple, which drives the catalytic cycle, has been estimated to ≈ 1.25 V, making the P^+ species the strongest oxidant found in biology. With an estimated midpoint potential of ≈ 0.75 V, the S_1/S_0 couple lies ≈ 0.5 V below the P^+/P couple, whereas the S_2/S_1 , S_3/S_2 , and S_4/S_3 midpoint potentials are estimated to ≈ 1 V. The overall free energy available to oxidize water is thus ≈ 3.75 V. This is sufficient to

drive the reaction at neutral pH (the minimal driving force required to reversibly oxidize water at pH 7 is 0.81 V per electron) but becomes low when the reaction has to occur at a pH close to 5, a value often quoted when the photosynthetic chain is at work.

The Rates of Oxidation of the Various S States

The rates of the various electron transfer reactions between the oxidized tyrosine Y_Z^{ox} and the S-states S_i are in the tens or hundreds of microseconds for the three lower S states. The S_4 to S_0 transition is significantly slower, in the millisecond time range, and concomitant with O_2 production and release. Based on the distance between the electron acceptor Y_Z^{ox} and the Mn cluster (7 Å) combined with the free-energy changes associated with these reactions, these rates appear much too slow for the reaction to be kinetically limited by the electron transfer proper. This has been taken as an indication of either redox-induced structural changes or/and a coupling with other processes rather than electron transfer such as proton transfer. Interestingly, a lag phase of a few tens of microseconds preceding the decay of S_4 into S_0 , which is accompanied by O_2 release, might evidence such events.

The Structure of the Catalytic Center and the Redox Events during the Reaction Cycle

Despite the tremendous amount of effort put into its elucidation, the structure and the valence of the Mn_4Ca cluster are still matters of strong debate. Indeed, the group of Yachandra has shown that the geometry and ligand environment of the Mn_4Ca cluster in the crystal structure suffers from the progressive reduction by the X-ray beam of the native high valence manganese cluster back to the Mn^{II} state and from a concomitant change in the delicate structural arrangement. Therefore, the combination of various spectroscopic methods such as electron paramagnetic resonance (EPR) and X-ray absorption spectroscopy (XAS) will still be required to provide a set of possible structures in the relaxed S_1 state and in the other higher oxidation states.

The Structure of the Manganese Cluster

The light-induced formation of the S_2 state results in a remarkable EPR signal, which was first reported by Dismukes and Siderer. This signal shows very rich hyperfine structures (it is commonly referred to as the 'multiline' signal), which have been taken as the spectroscopic signature of a mixed valence dinuclear $Mn^{III}-Mn^{IV}$ cluster. The multiline signal has provided experimental basis for modeling the structure and the valence state of the Mn_4Ca cluster in the S_2 state. EXAFS, pioneered by M. Klein, has provided valuable data on the distances separating the heavy atoms such as Mn or Ca, which are found in the catalytic center. These data put severe constraints on the possible structures. From both the EPR and EXAFS data, a dimer of di- μ -oxo $Mn^{III}-Mn^{IV}$ dimers has long been favored. However, several other structures with oxo-bridged Mn atoms are compatible with the data. Although not settled yet, the debate seems to be converging to structures

with three strongly magnetically coupled Mn and one weakly coupled Mn resulting in a mixed-valence cluster commonly called a 3 + 1 structure.

The Redox Events during the Catalytic Centers

As mentioned earlier, EPR and X-ray spectroscopies have also generously fed the debate on the valence state of the tetranuclear cluster during the catalytic cycle. Mn edge absorption spectroscopy has provided strong evidences for oxidation of a Mn atom during the S_0 to S_1 and S_1 to S_2 transitions. EPR and (less clearly) ultraviolet (UV) spectroscopies supported this view. It is now generally agreed that the valences of the Mn ions are $Mn^{III}_3Mn^{IV}$ in S_0 , $Mn^{III}_2Mn^{IV}_2$ in S_1 , and $Mn^{III}Mn^{IV}_3$ in S_2 . Based on a kinetic analysis, the S_4 is equivalent to the $[S_3Y_Z^{ox}]$ state. This seems to ground the accumulation of four oxidizing equivalents within the catalytic center (which would then include Y_Z , the Tyr161 of D1 in Figure 1, as a partner) before water is oxidized. Yet, the assignment of the substrate of the oxidation associated with the S_2 to S_3 transition is still an open question. This ambiguity mainly comes from the fact that depending on the group involved in these studies, EXAFS shows either a shift in the absorption edge consistent with a Mn oxidation, or little, if any, shift in the absorption edges, ruling out this latter assignment and favoring the formation of a radical species. Unfortunately, other spectroscopic methods such as EPR or UV absorption did not provide either unequivocal result. Recently, the EPR signature of the S_3 state has been characterized and corresponds to a spin = 3 state. As a consequence, the oxidation associated with the S_2 to S_3 transition likely occurs at the level of the cluster, that is, it involves either a Mn ion or a ligand belonging to the first coordination sphere (a bridging O atom or an amino acid ligand).

The Mechanism of Water Oxidation

In the above-mentioned model, oxidation of a bridging O atom is equivalent to the formation of a radical species. The possibility arises that this O atom originates from a water molecule which could therefore be oxidized during the S_2 to S_3 transition. If, on the contrary, the three successive steps leading to the formation of S_3 only involve Mn oxidation, an obvious conclusion is that water oxidation only takes place after the formation of S_4 (i.e., $S_3Y_Z^{ox}$). As discussed, this alternative could not be settled by spectroscopic approach. However, recent experiments on substrate binding tilt the scale toward the latter and further constrain the inventiveness when attempting to draw possible mechanism for water splitting.

Substrate/Bulk Water Molecule Exchange

In a series of very elegant studies, Messinger, Hillier, and Wydrzynski have used isotopically labeled water ($H_2^{18}O$) and measured the release of either O_2^{34} or O_2^{36} after a rapid mixing with PSII in the presence of unlabeled water. Most interestingly, they observed that substrate water may be exchanged with bulk water up to the S_3 state. This has been, until now, the strongest result in favor of a O–O bond-formation step occurring after S_3 is formed and thus during the S_4 to S_0 transition.

Proton Release during the Catalytic Cycle

The oxidation of two water molecules releases not only oxygen as a by-product but also four protons. From the pioneering work of Fowler, it is known that proton release accompanies the S_i to S_{i+1} transitions, which precedes the final S_4 to S_0 step during which O_2 is released. However, it is commonly agreed that these proton release events do not result from water chemistry. Indeed, proton transfers are often associated with redox changes either when the species which undergo the redox change is itself protonated or when the change in electrostatic potential resulting from the redox change shifts the affinity of a nearby acid group for proton. The two nonexclusive processes are likely to be at work, simultaneously or not, during the S_0 to S_1 , S_1 to S_2 , and S_2 to S_3 steps. The different groups which are deprotonated during these steps would be reprotonated by the protons produced during water oxidation. Although they most probably do not originate from water splitting, the proton release events occurring during the first three steps do play an important role in the overall water chemistry. They obviously compensate the charge accumulation which would otherwise result from three successive electron abstractions from a single catalytic unit. They control the thermodynamics of the enzyme by modulating the redox potential of the successive intermediate. In addition, the phenolic oxygen of the tyrosine side chain is protonated when Y_Z is in the reduced state, whereas Y_Z^{ox} is deprotonated. Its reduction must thus be accompanied by its reprotonation. This led G. Babcock to propose that Y_Z could act as H atom abstractor undergoing a simultaneous reprotonation and reduction at the expense of water molecule. Although it seems to be agreed that this process does not occur on each step, as previously proposed, this model is largely resorted to for the higher S-states transitions.

The Mechanisms for O_2 Formation

As discussed above, many issues regarding the catalytic cycle are still obscure. This may explain why there are almost as many mechanistic models for water splitting as groups studying this fascinating enzyme. It is beyond the scope of this article to present them all. As described, Mn atoms are oxidized during some, if not all, transitions between S states. Obviously, many models have incorporated these results and are based upon Mn-centered redox chemistry. Currently, three possible mechanisms are considered for the formation of the O = O double bond: (1) the coupling between two O bridging two Mn ions, (2) a mechanism which involves a terminal oxyl radical bound to a Mn ion (or bridging two Mn ions), and (3) a nucleophilic attack from a water molecule bound to the Ca^{2+} ion on the second water molecule bound to a Mn ion. In all cases, the two cofactors Ca^{2+} and Cl^- play a crucial role. Last, the tyrosine Y_Z could play a crucial catalytic role. As discussed above, the S_4 state is equivalent to the $[S_3Y_Z^{ox}]$ state so that Y_Z may be considered as a full member of the catalytic center. The close proximity between Y_Z and the Mn cluster supports this view.

Perspective

Obviously, important questions such as when and how does water oxidation chemistry come into play are still unsettled.

However, as illustrated by the recent crystallographic structures, the expected improvement in our knowledge of PSII at the atomic level should clarify if not solve some of the remaining ambiguities. Yet, it will not put an end to the sparking development of models and concepts, since identifying the different intermediate states during the overall reaction is a constantly renewed challenge, which is likely to be taken up by the field. Understanding the water chemistry became recently a renewed challenge for the biochemists and chemists owing to the increasing demand of new CO₂-free fuels.

Glossary

Adenosine triphosphate (ATP) The biochemical molecule utilized by the cells as energy source.

Alternative splicing A posttranscriptional process responsible for the maturation of a primary gene transcript and the generation of different messenger RNAs (mRNAs). Translation of these differently spliced mRNAs leads to protein products (isoforms) that differ only in the region affected by the alternative splice.

Calcineurin A serine/threonine phosphatase controlled by cellular calcium.

Calmodulin A calcium-binding protein expressed in all eukaryotic cells.

Calpains Proteases responsible for Ca^{2+} -regulated degradation of specific proteins.

Caspases Protein family responsible for degradation of specific proteins that contain recognizing sequences.

Their activation leads to signals of programmed cell death.

Cochlear hair cells Sensory cells in the organ of Corti of the inner ear, in synaptic contact with sensory as well as efferent fibers of the auditory nerve.

Isoform A protein structurally and functionally similar to a given protein.

Mechanoelectrical transduction (MET) channels Channels located in hair-cell stereocilia and permeant to Ca^{2+} .

PDZ domain A common structural domain of 80–90 amino acids found in the signaling proteins of bacteria, yeast, plants, viruses, and animals.

Plasma membrane One biological membrane separating the interior of a cell from the outside environment.

Stereocilia Apical structures of the hair cells of the inner ear that transduce mechanical energy into electro-chemical messages.

Structural and Regulatory Characteristics

The PMCA pump belongs to the family of P-type ATPases, which utilizes adenosine triphosphate (ATP) energy in the form of a phosphorylated enzyme intermediate (hence P-type) formed between the γ -phosphate of hydrolyzed ATP and an invariant D-residue in a highly conserved sequence of the pump molecules: SDKTGT[L/I/V/M][T/I/S]. The pump operates with a 1:1 Ca^{2+} /ATP stoichiometry as a Ca^{2+} : H^{+} exchanger: the matter of Ca^{2+} / H^{+} stoichiometry is still controversial. The pump has high Ca^{2+} affinity and a multitude of agents that modulate it. The K_d of the pump for Ca^{2+} , which is 10–20 μM in the resting state, decreases to less than 1 μM following calmodulin interaction. Acidic phospholipids also increase the Ca^{2+} affinity of the pump. Even if the molecular mechanism of the activation by phospholipids is obscure, it could be physiologically meaningful: it has been calculated that in the membrane environment the pump is probably permanently activated by acidic phospholipids to about 50% of its maximal activity.

Structurally, the pump is predicted to consist of 10 transmembrane domains, two large intracellular loops, and of N- and C-terminal cytoplasmic tails (Figure 1). The 90-residue N-terminal tail contains a consensus binding site for the 14-3-3 protein, which plays an inhibitory role on pump activity. The first cytosolic loop between transmembrane domains 2 and 3 is considered the transducer domain. It contains one of the two sites that mediate the activation by acidic phospholipids and one of the two sites for the autoinhibitory interaction with the calmodulin-binding domain. This loop also contains site A, which is one of the two main sites of the

alternative splicing that generates pump variants. Interestingly, the A-splice-site-insert also plays a key role in the apical targeting of PMCA.

The cytosolic loop that connects transmembrane domains 4 and 5 contains the catalytic center that includes the ATP-binding site and the aspartate residue that forms the acyl phosphate intermediate. It also contains the second binding site for the C-terminal calmodulin-binding domain. The C-terminal tail contains the main regulatory sites for the activity of the pump: the calmodulin-binding domain (which also binds acidic phospholipids), consensus sites for protein kinases A (PKA) and C (PKC), and high-affinity allosteric Ca^{2+} -binding sites. The calmodulin-binding domain of the PMCA pump acts as an autoinhibitory domain, binding to receptor sites in the first and second cytoplasmatic loops of the pump. Calmodulin would remove the domain from the binding sites, freeing the pump from autoinhibition.

The C-terminal region of the pump is also the target of isoform-specific phosphorylations by PKA and PKC. Phosphorylation could influence the regulation of the pumps either directly (e.g., by de-inhibiting it) or indirectly (e.g., via interference with calmodulin regulation). Recent studies have shown that PKC affects the various PMCA isoforms and splicing variants in different ways according to variations in the C-terminal sequence: the phosphorylation may activate the pump, inhibit it, or have no effects. As for PKA, its consensus site has only been described in isoform 1 of the pump. The PMCA pump is also a substrate of intracellular proteases, as its C-terminal tail contains target sequences for the Ca^{2+} -dependent protease calpain and for caspase 1 and 3. Calpain cleaves the pump in the calmodulin-binding sequence, leading

Figure 1 Topography model of the plasma membrane Ca^{2+} -ATPase. The 10 putative transmembrane domains are numbered and indicated by shadow boxes, PL indicates the phospholipid-binding domain downstream site A of alternative splicing, D indicates the catalytic aspartate. ATP and CaMBD indicate the ATP-binding site and the Calmodulin-binding domain, which contains the site C of alternative splicing.

to permanent activation of the pump. Both activation and inactivation have been described for caspases 1 and 3 action on PMCA2 and 4.

The C-terminal domain of the pump also contains an important site of alternative splicing, site C. C-site splicing occurs in all pump isoforms (albeit with varying degrees of complexity) and causes the inclusion of one (or two) additional exons, or of a portion of exons. The insertion has structural and functional consequences: it leads to the truncation of the pump due to a frame shift in the coding region, and alters, for instance, the pH sensitivity of the interaction of calmodulin with the calmodulin-binding domain. In general, the truncated isoforms have much decreased affinity for calmodulin. Surprisingly, however, the full length and the truncated variants expressed in living cells appear to have the same ability to restore the cytosolic Ca^{2+} transient generated by cell stimulation: the finding suggests that *in vivo* calmodulin may not be the only factor regulating PMCA activity.

The C-terminal domain also mediates the interaction with PDZ (postsynaptic density protein, PSD-95; Drosophila disk large tumor suppressor, Dlg; Zonula occludens-1, ZO-1) domains of different proteins, and mediates PMCA dimerization (which also activates the pump). The interaction with PDZ domains is apparently limited to the full-length splice isoforms, as the C-terminally truncated variants lack the consensus site for its binding. PMCA has been reported to interact with PDZ-domain-containing proteins involved in the recruitment and maintenance of membrane proteins in specific membrane domains, such as members of the membrane associated guanylate kinase (MAGUK) family, that is, synapse-associated protein (SAP), calcium-calmodulin-dependent serine protein kinase (CASK), the Na/H exchanger regulatory factor 2, PISP, and the Ania3/Homer protein. These proteins could contribute to targeting and retention of PMCA in specialized domains. The increased local pump concentration could regulate Ca^{2+} signaling. The PDZ-binding domain also directs the interaction of one of the PMCA-isoforms (4b) with nitric oxide synthase 1 (NOS-1) in a ternary complex with alpha-syntrophin.

The double interaction would thus downregulate the production of NO by decreasing Ca^{2+} in the immediate vicinity of the synthase: that is, the pump could function as a modulator of signal transduction, in addition to regulating cell Ca^{2+} .

Isoforms and Tissue Distribution

The four basic PMCA isoforms (the PMCA is the product of four separate genes) have tissue-specific expression. While PMCA1 and PMCA4 are expressed in most tissues, PMCA2 and 3 are found in a restricted number of tissues, among them in brain, striated muscle, and the mammary gland. In particular, PMCA2 is abundant in specialized cells such as cerebellar Purkinje neurons and cochlear hair cells, and it is also present in the uterus and in lactating mammary glands. It is also expressed in significant amounts in the liver and kidney. PMCA3 distribution is more restricted, the choroid plexus expressing significant amounts of it.

The transcript of each of the four genes encoding PMCA pumps is subject to alternative splicing: the sites where it occurs are named A, B, and C. Of the large number of splice variants theoretically possible, about 30 have been detected at the RNA or protein levels (Figure 2). Alternative splicing at site A and C occurs for all four isoforms (however, PMCA1 is never spliced at site A). Alternative splicing at site B has been described only for human isoform 1 and 4 and it could be artifactual (see below). Splice site A is located upstream of one of the regulatory binding sites for acidic phospholipids (see above) and involves up to three exons that can be optionally inserted or excluded. In PMCA3 and 4, a single exon may be included or excluded in the mature messenger RNA (mRNA), thus generating the x and z splice variants, respectively. The situation in PMCA2 is more complex: in the human pump, three exons of 33, 60, and 42 nt, alternatively used, could in principle originate eight different variants. However, only four of them have so far been detected as mRNAs in a variety of tissues. Variant w includes all three exons, variant z excludes all three exons, variant x includes the 42 nt exon, and variant y includes the 33 and 60 nt exons. This alternative splicing was shown to be essential in the apical targeting of PMCA and could thus also be involved in the regulation of the pump distribution in specialized portions of the plasma membrane (directly or through the interaction with other molecular determinants). Despite the splice site A being contiguous to one of the two phospholipid-binding domains, the insertion of additional exons does not affect the phospholipid regulation of PMCA isoforms. As mentioned, the splicing at site B may be an artifact, as its occurrence *in vivo* has been a point of controversy. It has been proposed to remove a C-terminal 108 nt segment, leading to the loss of the 10th transmembrane domain and causing a reorganization of the pump topology. Splice site C is located in the C-terminal of the PMCA protein, within the calmodulin-binding domain: the inclusion of a large exon (154–175 nt) alters the C-terminal half of the domain in all isoforms and changes the reading frame of the remaining C-terminal tail. This splicing is thus responsible for the generation of variant a, truncated after the first 12 residues of the calmodulin-binding domain. The variant has reduced responsiveness to calmodulin with respect to the full-length

Figure 2 Linear representation of the alternative splicing options at site A (a) and site C (b) of the PMCA transcripts. Exons are indicated by shadow boxes and introns by the black lines. The numbers in the boxes represent the nucleotide number of each exon.

variant (termed ‘variant *b*’). Lower Ca-calmodulin affinity and a significantly elevated basal pumping activity are general characteristics of the *a* splice variants in comparison with the *b* variants.

Interestingly, the expression of the PMCA pumps is transcriptionally regulated by Ca^{2+} itself. The phenomenon has been studied on cultured neurons and is correlated to their maturation. In cerebellar granule cells, as Ca^{2+} concentration in the cytoplasm increases, the pattern of expression of the PMCA pumps undergoes a dramatic rearrangement: isoforms 2 and 3 become strongly upregulated, whereas isoform 1 undergoes a splicing switch which generates high levels of the truncated *a* variant. By contrast, PMCA4 disappears in a process that is calcineurin dependent. The reprogramming of the transcription of PMCA is essential to the survival of the

developing neurons: the regulation of PMCA expression may thus be critical to the survival of cells exposed to pathological increases in intracellular Ca^{2+} . Parallel amplification of Ca^{2+} influx and efflux pathways may enable differentiated neurons to precisely localize Ca^{2+} signals in time and space. Similarly, in rat hippocampal neurons, transcripts for all isoforms of the PMCA pump have been found to be strongly upregulated during the second week in culture, the overall increase in Ca^{2+} extrusion systems being accompanied by changes in the expression and cellular localization of different isoforms. The accumulation of PMCA in dendrites and dendritic spines coincided with the functional maturation of these neurons, underlining the importance of the proper spatial organization of the Ca^{2+} extrusion systems in synaptic function and development.

Figure 3 Schematic model of the hair bundle. The plasma membrane Ca^{2+} pump and the mechanotransduction channel (MET) are indicated. PMCA2 mutations reduce the ability of the PMCA to extrude Ca^{2+} , decreasing the endolymphatic Ca^{2+} concentration, thus increasing the open probability of MET channels.

Role in Physiology and Pathology

PMCA pumps are expressed ubiquitously; thus, they are unlikely candidates as molecules that could mediate cell-specific processes. However, the existence of so many PMCA variants (basic isoforms and alternative spliced forms), the finding on knockout mice for the specific PMCA isoforms, and studies on the mechanisms modulating their cell/tissue-specific distribution indicate that PMCA pumps may play important roles as signaling molecules, in addition to having a constitutive role as Ca^{2+} -housekeeping enzymes.

The ablation of isoforms 2 and 4 in mice has indeed revealed that they are important in specialized biological processes. PMCA2 plays an essential role in the hearing process, since it dissipates with peculiar kinetics the Ca^{2+} transients generated by the opening of the mechanoelectrical transduction (MET) channels in the stereocilia of cochlear hair cells (Figure 3). Mutations in the PMCA2 pumps in hereditary deafness impair the longer-term export of Ca^{2+} from hair cells, but not their ability to respond to a sudden increase of Ca^{2+} . This suggests that the mutated pumps reduce the extracellular Ca^{2+} gradient in the endolymph surrounding the hair cells, compromising the adaptation process responsible for the control of the opening of MET channels. Interestingly, the PMCA2 isoform has another peculiar function in the mammary gland: its activity is responsible for the high content of Ca^{2+} in the milk. PMCA2 is strongly upregulated in lactating mammary gland, and PMCA2 null mice have 40% less Ca^{2+} in the milk.

PMCA4 is crucial to male fertility: in mice, its ablation reduces sperm motility, probably resulting from Ca^{2+} overload and mitochondrial damage. Interestingly, PMCA4 is also essential for the modulation of the activity of the calcium/calmodulin-dependent neuronal nitric oxide synthase (nNOS)

which controls nitric oxide production, which is important in the regulation of excitation–contraction coupling of the heart. It has been shown that PMCA4b also regulates cardiac contractility *in vivo* through its interaction with nNOS.

PMCA defects have been described in a large number of disease conditions, among them those linked to the oxidative stress in several tissues, particularly brain, in brain ischemia, diabetes, atherosclerosis, aging, neurodegenerative diseases, and various disturbances of Ca^{2+} metabolism. PMCA defects have also been reported in various cancer types, in line with accumulating evidence on the involvement of Ca^{2+} homeostasis dysfunction in the process of malignant transformation. The genetic diseases involving the PMCA pump are best characterized: a number of dysfunctions linked to the ablation, or to partial disruptions, including point mutations, of its genes, have been described in mice. So far, the only identified spontaneous human disease related to a PMCA pump (isoform 2) defect is the form of hereditary deafness described above.

Genetic Manipulations of PMCA and Sodium Calcium Exchanger (NCX)

Knockout mice have been developed and the phenotypes studied for PMCA1, PMCA2, and PMCA4, but not yet for PMCA3. As this isoform is widely expressed in developing embryos, it may be essential for normal gestation.

The ablation of the PMCA1 gene has resulted in early embryonic lethality in homozygotes, underlying the essential role of PMCA1 in the early stages of development and in organogenesis, in line with its suggested housekeeping function. Heterozygotes, by contrast, appeared healthy; however, loss of one copy of the PMCA1 gene in mice with a PMCA4 null

background led to increased propensity to apoptosis in the smooth muscles of blood vessels, possibly due to Ca^{2+} overload. The ablation of the PMCA2 gene revealed its involvement in the hearing process: the phenotype of the PMCA2 knockout mice was characterized by balance impairment and hearing loss. The study of the vestibular inner ear revealed the absence of the otoconia and the progressive degeneration of the hair cells beginning 10 days after birth. The PMCA2 pump is probably also important to general neuronal Ca^{2+} homeostasis since PMCA2 null mice showed a significant reduction in the number of spinal cord motor neurons and abnormalities in Purkinje neurons. However, the balance defect was apparently not due, as could in principle have been expected, or was only partially due, to a cerebellar dysfunction. It was apparently related to the absence of the Ca-carbonate crystals of the otoconia embedded in the otolithic membrane overlying the sensory epithelium that sense gravity and linear acceleration in the inner ear. In keeping with the high level of expression of PMCA2 in the mammary gland, the ablation of its gene, in addition to generating the hearing loss phenotype, also strongly reduced the concentration of Ca^{2+} in the milk.

The ablation of the PMCA4 gene failed to cause a very evident general pathological phenotype, but local defects were present. This is interesting, as PMCA4 is also widely expressed, and has also been proposed to play a housekeeping role. However, it has now become evident that PMCA4 plays more specialized roles, and is not only essential for the general function of controlling Ca^{2+} homeostasis in all cells. One prominent defect caused by PMCA4 dysfunction was male infertility, reflecting the dominance of the PMCA4 pump in the testis, where it represents more than 90% of the total PMCA protein. The ablation of the PMCA4 gene produced other localized dysfunctions, for instance, in the modulation of the Ca^{2+} signals in B-lymphocytes and in the contractility of vascular or bladder smooth muscles.

Important physiological functions of the PMCA4 isoform were revealed by studies on mice overexpressing it rather than by ablating it. Early studies in which the PMCA4 pump had been expressed specifically in the myocardium of the rat, and in vascular smooth muscle cells in mice, had indicated a role in the modulation of myocardial growth and hypertrophy. They have also indicated a role in the regulation of the peripheral vascular tone, as the mice displayed increased peripheral blood pressure.

Concluding Remarks

To respond dynamically to the changing needs of Ca^{2+} signaling, cells must be able to precisely control the type, amount, localization, and activation of Ca^{2+} transporters. This control is performed in two ways: through the variable expression of Ca^{2+} transporters with different biochemical characteristics and through the fine modulation of their function by expressing differently active isoforms in response to the local or temporal cell demands. The cell also modulates the activity of its transporters by choosing specific molecular partners: in the

case of the PMCA pump, the interaction with different proteins contributes to regulate the activity of the pump such as in the case of calmodulin or 14-3-3 protein, but also to generate a special micro-environment where Ca^{2+} concentration can be finely modulated to optimize the activity of other enzymes, such as in the case of the cardiac NOS. Thus, the PMCA pump not only contributes to maintain the general Ca^{2+} homeostasis but also operates as an essential actor in specific signal transduction pathways.

Glossary

Cytochrome *b₆f* complex Large multisubunit complex located in the thylakoid membrane that mediates electron transport between plastoquinone and plastocyanin (PC). Cyt *f*, a member of this complex, donates electrons directly to PC.

P700 Chlorophyll dimer in the reaction center of PSI which is oxidized by light and reduced by PC.

Photosystem I Large multisubunit complex located in the thylakoid membrane which accepts electrons

from PC and donates them to ferredoxin. It contains the primary electron donor P700 and acceptors A₀, A₁, and Fx.

PsaA, PsaB, and PsaF Protein subunits of photosystem I (PSI).

Thylakoid Portion of the inner membrane system of the chloroplast where the light reactions take place and where the cytochrome *b₆f* complex and PSI are located.

The photosynthetic electron transport chain of higher plants, algae, and cyanobacteria consists of two light reactions (photosystem II (PSII) and photosystem I (PSI)), which act in series to produce molecular oxygen, reduce nicotinamide adenine dinucleotide phosphate (NADP⁺) to nicotinamide adenine dinucleotide phosphate-oxidase (NADPH), and synthesize adenosine triphosphate (ATP). The cytochrome *b₆f* complex is a large multisubunit complex involved in the transfer of electrons from PSII to PSI. Plastocyanin is an ~10-kDa Cu protein which acts as a mobile electron carrier, located in the lumen of the chloroplast thylakoid, which shuttles electron from cytochrome *f* (Cyt *f*) in the cytochrome *b₆f* complex to P700 in PSI. It can be replaced by an Fe-containing cytochrome (cytochrome *c₆*) in some green algae and cyanobacteria under conditions of copper deficiency.

Plastocyanin Structure

The Copper Center

Plastocyanin (PC) is a β -sheet protein (Figure 1) with a Cu atom that acts as the redox center. The Cu atom is coordinated to four amino acid residues (H87, H37, S84, and M92) in a distorted tetrahedral geometry. The distorted tetrahedral geometry of the Cu center together with the protein matrix promotes efficient electron transfer between Cyt *f* and P700. Electrons enter and leave PC via the H87 ligand to the copper, which is located on the surface of the PC molecule (Figures 1 and 2).

The Surface of the PC Molecule

Higher plant and green algal PCs

Figure 2(a) depicts the surface of spinach PC which is a typical representative of higher plant and green algal PCs. There are two important features. The first is the patch of hydrophobic residues (green in Figures 2(a) and 2(b)) that surround the H87 ligand to the copper. These residues – including G10, L12, G34, F35, P36, L62, P86, G89, and A90 – are either conserved or replaced with similar residues in all PCs. They provide a

hydrophobic binding surface for both Cyt *f* and PSI (see below). The second feature consists of two patches of negatively charged residues surrounding Y83 (yellow in Figures 2(a) and 2(b)). Negatively charged residues are shown in red and positively charged ones are shown in blue in Figure 2. The lower patch consists of anionic residues #42–44 and either #45 or #79. The upper patch consists of anionic residues #59–61 in most higher plant PCs. In a few higher plant species and in all green algae, one of the anionic residues in the upper patch is deleted and is replaced by a glutamate at position #85. Also, all higher plant and green algal PCs contain an additional anionic residue at either position #51 or #53. Thus, there are a total of eight anionic residues that contribute to large negatively charged electrostatic field surrounding Y83.

Cyanobacterial PCs

Cyanobacterial PCs are similar to those from higher plants and green algae in that a patch of hydrophobic residues surrounds the H87 ligand to the Cu (Figure 2(b)) (residues from cyanobacterial PCs are numbered so as to be consistent with those from higher plant PCs). However, the distribution of charged residues on the surface of cyanobacterial PCs is quite different from that observed for higher plants and green algae. The only conserved anionic residue is D42. Instead, there are a series of positively charged residues on PC including R88, K44, and K51 that contribute to a positively charged electrostatic field surrounding Y83.

The Interaction of PC with Cyt *f*

The Structure of Cyt *f*

Cyt *f* is also a β -sheet protein with two domains. The heme is located on the large domain. The sixth ligand to the heme is the amino group of Y1 which may provide a pathway of electron transfer from the heme to H87 on PC. Y1 and the heme are surrounded by a patch of highly conserved hydrophobic residues. Cyt *f*s from higher plants and green algae have a highly conserved basic patch consisting of five residues (K58, K65,

Figure 1 The structure of spinach plastocyanin: the copper center. The copper atom in PC (dark blue) is coordinated to two histidines (H87: light green; H37: dark green), C84 (yellow) and M92 (cyan). PC structures are taken from the Protein Data Bank from Berman HM, Westboro J, Feng Z, et al. (2000) The Protein Data Bank. *Nucleic Acids Research* 28: 235–242, and displayed using the Program GRASP from Nicholls A and Honig B (1991) A rapid finite-difference algorithm, utilizing successive over-relaxation to solve the Poisson–Boltzmann equation. *Journal of Computational Chemistry* 12: 435–445.

Figure 2 Surface residues on PC. H87, green; Y83, yellow; hydrophobic, cyan; cationic, blue; anionic, red: (a) spinach PC and (b) cyanobacterial PC from *P. lamosum*. Other conditions are the same as for Figure 1.

K66, K187, and R209 in turnip Cyt *f*). The negatively charged residues on higher plant and algal PCs are attracted to the positive patch on Cyt *f*. By contrast, Cyt *f* from the cyanobacterium *Phormidium lamosum* has a large number of negatively charged residues on its surface that attract the positively charged residues on cyanobacterial PCs.

Complex Formation between PC and Cyt *f*

Figure 3 depicts a complex between spinach PC and turnip Cyt *f* determined by nuclear magnetic resonance (NMR). Two types of interactions are observed. First, there is an electrostatic attraction between cationic residues on Cyt *f* (blue) and the anionic residues surrounding Y83 on PC (red). These

Figure 3 Complex formed between turnip Cyt *f* and spinach PC. Backbone of Cyt *f*, gray; backbone of PC, cyan. Other colors are the same as for Figure 2. Model 1 taken from Ubbink M, Ejdeback M, Karlsson BG, and Bendall DS (1998) The structure of the complex of plastocyanin and cytochrome *f*, determined by paramagnetic NMR and restrained rigid-body molecular dynamics. *Structure* 6: 323–335.

electrostatic interactions serve to bring the two molecules together and to orientate them properly. Evidence for electrostatic interactions comes from cross-linking, chemical modification, and mutagenesis experiments. Second, hydrophobic residues surrounding the heme and Y1 on Cyt *f* interact with those surrounding the H87 ligand and the Cu on PC. These hydrophobic interactions anchor the two proteins in the proper orientation for efficient electron transfer from the heme and Y1 on Cyt *f* to H87 and the Cu on PC. Complexes formed between *Phormidium* Cyt *f* and *Phormidium* PC show a greater influence of hydrophobic as opposed to electrostatic interactions.

The Interaction of PC with PSI

The Structure of PSI

Recently, the structure of PSI from *Synechococcus elongatus* has been determined at a resolution of 2.5 Å by X-ray crystallography. A simplified model of PSI is presented in Figure 4. Two regions of PSI have been implicated in PC binding. The first region includes the two largest subunits, PsaA and PsaB. These two subunits form a heterodimer containing P700 as well as the early electron acceptors A_0 , A_1 , and F_x . The second region includes the small subunit PsaF.

The Involvement of the PsaA and PsaB Subunits in Hydrophobic Interactions with PC

The PsaA–PsaB heterodimer has a 10-Å depression which has been postulated to form a binding pocket for PC and cyt c_6 (Figure 4). Two surface-exposed hydrophobic helices line the binding pocket. One is part of PsaA and extends from residue #646 to residue #664; the second is located on PsaB and extends from residue #Y621 to residues #N639. Also, W655 on PsaA and W631 on PsaB are located in these helices and point toward the binding pocket. It has been postulated that these residues may be involved in the transfer of electrons

Figure 4 Model of the interaction of PC with PSI in higher plants and algae. The interactions of PC (blue) with (1) the PsaA and PsaB subunits of PSI (green) and (2) the N-terminal positively charged helix of PsaF (red) are shown. The hydrophobic helices in the *ij* loops of PsaA and PsaB that have been postulated to be part of the binding pocket are also shown.

from PC to P700. The observation that two mutants of residues located in the surface-exposed PsaB helix (W627F and E613N) caused significant inhibition of electron transport from PC to P700 support the hypothesis that these helices participate in the binding of PC to PSI.

Involvement of the PsaF Subunit in Electrostatic Interaction between PC and PSI in Higher Plants and Green Algae

The PsaF subunit in green plants and algae has been implicated in PC binding to PSI (Figure 4). The evidence for this is as follows. First, removal of PsaF by either detergent treatment or mutagenesis inhibits the fast phase of electron transfer from PC to P700. This rapid phase has a half-time of ~11 ps and represents electron transfer from PC to P700 in preformed PC–PSI complexes. Second, mutagenesis of residues #42–45 in the lower patch of PC inhibited the fast phase of electron transfer. By contrast, mutagenesis of the upper patch (residues #59–61) had very little effect. The N-terminal portion of PsaF consists of an amphipathic helix in which six lysine residues are lined up on one side of the helix. Third, mutagenesis of the lysine residues in this region of PsaF inhibited cross-linking and electron transfer from PC to P700; the greatest effect was observed for K23Q. Fourth, PC can be chemically cross-linked to PsaF. It was found that residues from the lower acidic patch of PC (#42–45) were cross-linked to residues #10–24 on PsaF, and residues from the upper acidic patch (#59–61) were cross-linked to residues #24–51 on PsaF.

The situation is different in cyanobacteria. Cyanobacteria show no rapid phase of electron transfer from PC to P700. In fact, the rate of electron transfer in cyanobacteria is ~2 orders of magnitude lower than that observed in green

plants or algae. Also, removal of PsaF has no effect. An examination of PsaF in cyanobacteria shows that it lacks the N-terminal lysine-rich helix found in higher plants and green algae. However, when a chimeric PsaF, made up of the N-terminal sequence from *Chlamydomonas* PsaF and the C-terminal sequence from the cyanobacterium *Synechococcus*, was placed in *Synechococcus* cells, rapid electron transfer was observed between *Chlamydomonas* PC (and cyt *c₆*) and P700 which had the same characteristics as observed in *Chlamydomonas* cells. However, there is some evidence for electrostatic effects in cyanobacteria as removal of the negative charge of D42 on a cyanobacterial PC increased the rate of electron transfer to P700, whereas removal of the positive charge of R88 decreases it.

In conclusion, binding of PC to PSI in green plants and algae is similar to its binding to Cyt *f* in that electrostatic forces steer PC (and cyt *c₆*) to the hydrophobic binding sites on PSI (Figure 4) where electron transfer to P700 occurs in a rapid and efficient manner.

Glossary

Autocoid An autopharmacologic substance that has potent local activity.

G-protein-coupled receptor A class of receptors for a diverse set of ligands including hormones, lipid inflammatory mediators, and chemokines that use associated trimeric G proteins for intracellular signal transduction.

Lipopolysaccharide A component of the cell wall of Gram-negative bacteria containing both lipid and

carbohydrate moieties that instigates many innate immune responses such as secretion of cytokines, activation of macrophages, and expression of leukocyte adhesion molecules. Synonymous with endotoxin.

Platelet-activating factor (PAF) A lipid autocoid.

Zymosan An insoluble protein–carbohydrate complex from the cell wall of yeast.

The platelet-activating factor (PAF) receptor is a member of the G-protein-coupled seven-transmembrane receptor superfamily. PAF receptor stimulation and the subsequent intracellular signaling events are involved in both physiological and pathophysiological processes but mainly participate in transcellular communication during inflammatory events. PAF receptor activation is instigated by the binding of PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine), a potent lipid mediator, which produces biological responses at very low molar concentrations (10^{-10} M).

Platelet-Activating Factor

Although PAF was first identified in the 1970s as a soluble mediator responsible for platelet aggregation when IgE-sensitized basophils were challenged with antigen, researchers have since established that PAF has diverse and potent biological activities. In addition to platelet aggregation, PAF can activate monocytes/macrophages, induce hypotension and bronchoconstriction, stimulate glycogenolysis, and participate in ovulation and ovoidimplantation. In addition, PAF has a profound role in acute inflammation, allergic disorders, and endotoxic and anaphylactic shock. Unlike other cytokines and inflammatory mediators, PAF is not synthesized and stored in a preformed state; rather, it is rapidly synthesized in response to specific stimuli. Cells that participate in inflammatory reactions including monocytes/macrophages, polymorphonuclear neutrophils, eosinophils, basophils, and platelets all rapidly produce PAF upon stimulation. Most cells that produce PAF also express PAF receptors. Therefore, PAF can operate in an autocrine, paracrine, or juxtacrine fashion. For instance, stimulated monocyte/macrophages release a majority of the PAF synthesized into the fluid phase and this PAF can interact with PAF receptors on its own cell surface (autocrine) or can bind to PAF receptors on other inflammatory cells in the immediate vicinity (paracrine). In the case of endothelial cells and leukocytes, synthesized PAF remains partially cell associated. For endothelial cells, this PAF is

presented on the cell surface for the juxtacrine activation of infiltrating leukocytes. The biological responses resulting from PAF receptor activation occur as a consequence of direct interactions of the mediator with receptors on target cells or through indirect secondary signaling effects.

In 1979, Hanahan and colleagues defined the chemical structure of this novel ether phospholipid, and the chemical structure of the lipid is presented in [Figure 1](#). The PAF molecule contains several specific structural features which are necessary for its potent biological activity. PAF contains an *O*-alkyl ether residue at the *sn*-1 position of the glycerol backbone. The ether-linked side chain can vary in chain length and degree of saturation but the 16:0 moiety is predominant. The 18:0-, 17:0-, and 18:1-containing molecules also occur naturally, but these molecules exhibit several orders of magnitude-less biological activity. There is an acetyl moiety at the *sn*-2 position of PAF and removal of this acetate group by the enzyme PAF acetylhydrolase generates lysoPAF which is biologically inactive. In addition to the strict structural requirements at the *sn*-1 and *sn*-2 positions, PAF requires a polar head group containing choline at the *sn*-3 position for specific PAF binding and functional activation of the PAF receptor. Both PAF synthetic and degradative enzymes recognize these unique structural features of PAF.

PAF is synthesized from 1-*O*-alkyl containing glycerolphosphocholines enriched with arachidonic acid at the *sn*-2 position. There are two distinct synthetic routes for PAF production, a remodeling and a *de novo* pathway. The *de novo* pathway produces low levels of PAF and has been attributed to the formation of constitutive levels of PAF for normal physiological actions. The remodeling pathway is the predominant route of PAF production by cells and tissues in response to systemic or local injury and trauma. Such stimulants for PAF generation can be microbial agents such as lipopolysaccharide (LPS) and zymosan or biological agents such as cytokines, chemotactic peptides, thrombin, and calcium ionophores.

Stimulating the remodeling pathway generates PAF in a two-step process. PAF synthesis begins with the activation of

Figure 1 Chemical structure of PAF.

cytoplasmic phospholipase A_2 (cPLA $_2$) which preferentially cleaves the arachidonate at the *sn*-2 position. Therefore, the reaction releases arachidonic acid during the formation of lyso-PAF. The arachidonic acid is converted to eicosanoids via the lipoxygenase or cyclooxygenase pathways. Production of PAF occurs concomitant with the production of the eicosanoids which also contains far-reaching biological activities. The essential role of cPLA $_2$ in the synthesis of PAF has been confirmed from cPLA $_2$ knockout animals. In the second step of PAF generation, lysoPAF is converted to PAF by the actions of acetyl-CoA-lysoPAF acetyltransferase (LysoPAFAT). After nearly two decades of effort, the LysoPAFAT was recently cloned and characterized. This bifunctional enzyme also contains lysophosphatidylcholine acyltransferase activity and, therefore, participates in not only PAF synthesis but also membrane phospholipid synthesis. Inflammatory stimuli switches the activity of the enzyme from predominately membrane biogenesis to PAF synthesis.

Although the synthesis of PAF is tightly controlled, PAF-like species capable of binding and activating the PAF receptor can arise from the oxidation of unsaturated phosphatidylcholine. These ligands of the PAF receptor arising from oxidative damage of membrane phospholipids contribute to dysfunctional PAF receptor signaling and to the pathophysiological events associated with numerous disease entities.

PAF and PAF-like phospholipids are rendered biologically inactive via the actions of specific Ca^{+2} -independent phospholipases A_2 called 'PAF acetylhydrolases'. Three unique PAF acetylhydrolases are known to exist: two intracellular and one secreted form. These acetylhydrolases play a crucial role in terminating inflammatory responses elicited by both PAF and PAF-like phospholipids. Elevated plasma levels of the secreted PAF acetylhydrolase (also called 'lipoprotein-associated phospholipase A_2 ; Lp-PLA $_2$ ') were observed in patients with coronary artery disease but the exact role of plasma PAF-acetylhydrolase in cardiovascular diseases and atherosclerosis remains controversial.

Many of the biological and pathophysiological actions of PAF were initially investigated using specific PAF receptor antagonists. These PAF receptor antagonists include compounds with structural resemblance to PAF such as CV-3988 (phospholipid analogs) and nonstructural antagonists such as WEB 2086 and BN 50739. Classical ligand-binding experiments demonstrated specific PAF binding in numerous tissues and cells, including platelets, neutrophils, macrophages, mononuclear leukocytes, eosinophils, Kupffer cells, epithelial cells, and endothelial cells.

The unique structural features of PAF, the existence of PAF receptor antagonists, and direct binding data utilizing radiolabeled PAF, as well as biochemical evidence for the diverse

activation of second-messenger signal cascades, all provided evidence for the existence of specific PAF receptors. Confirmation that PAF signaling occurs through receptor-mediated mechanisms was affirmed in 1991 with the molecular identification of the first receptor cloned for a lipid mediator by Shimizu and colleagues.

PAF Receptor Structure

Numerous attempts by investigators to isolate the PAF receptor proved unsuccessful. The eventual cloning of the PAF receptor was accomplished in an elegant strategy involving expression cloning of a guinea pig lung complementary DNA (cDNA) library in *Xenopus laevis* oocytes. The initial cDNA library, constructed from size-fractionated poly (A) RNA, was converted *in vitro* into cRNA using the phage DNA as a template. Pools of cRNA were introduced into oocytes and a PAF-induced electrophysiological detection of G-protein-coupled phosphatidylinositol (PI) turnover was assayed. A single PAF-receptor cDNA sequence isolated by the cloning strategy predicted a protein of 342 amino acids and a calculated molecular mass of ~ 39 kDa. However, immunological detection of the PAF receptor on Western blots revealed an apparent MW of 69 kDa suggesting the presence of posttranslational modifications of the receptor. In fact, two potential N-linked glycosylation sites were identified in the PAF receptor cDNA sequence. Hydrophathy plot analyses of the deduced PAF receptor amino acid sequence predicted the presence of seven transmembrane-spanning domains within the PAF receptor. A schematic representation of the PAF receptor is presented in **Figure 2**. Through site-directed mutagenesis studies, several key features of the PAF receptor have been determined. Similar to other G-protein-coupled receptors, the ligand-binding site is defined in three dimensions by amino acids from several of the transmembrane-spanning regions. Mutations in membrane-spanning segments II (N58A and D63A), III (N100A, T101A, and S104A), and VII (D289A) increased affinity of PAF binding while mutations in V (H188A), VI (H248A, H249A, and Q289A), and VII (Q276A and T278A) lowered the affinity of PAF for the receptor. The third intracellular loop of the receptor is coupled to PI turnover. The C-terminal cytoplasmic tail of the receptor containing a cluster of serine and threonine residues are candidate sites for phosphorylation by G-protein receptor kinases, and are critical for agonist-induced desensitization.

Subsequent to the isolation of the guinea pig cDNA, cDNA for numerous other species was isolated by cross hybridization. The PAF receptor maintains $\sim 74\%$ sequence identity between the various species identified to date. Because the PAF receptor messenger RNA (mRNA) is present in only subsets of cells, Northern blot hybridizations have limitations in detecting PAF receptor expression in some tissues. The relative tissue abundance among different species varies but, in general, lung, neutrophils, monocytes, macrophages, placenta, small intestine, heart, liver, kidney, brain, and spleen have detectable PAF receptor expression.

The isolation of human PAF receptor cDNAs identified two unique 5'-noncoding regions designated transcript 1 and transcript 2. The tissue- and cell-type distribution of these two

Figure 4 PAF receptor intracellular signaling pathways. See text for abbreviations.

is controlling the availability of PAF. This mechanism includes regulation of both PAF synthesis and release, and the rapid inactivation of PAF by PAF acetylhydrolases. Other mechanisms of regulation of this signaling system are intrinsic to the PAF receptor and include homologous desensitization to repeated or sustained administration of PAF. Desensitization of the PAF receptor leads to decreased PAF-induced cellular responses in guanosine triphosphatase (GTPase) activity, IP_3 production, and calcium mobilization. The carboxy terminus of the PAF receptor is the target for phosphorylation required to desensitize the receptor. PAF receptor desensitization may occur by uncoupling of the receptor to G proteins and by ligand-induced internalization of the receptor.

As opposed to the fairly rapid process of controlling PAF availability and PAF receptor responsiveness, long-term regulation of the PAF receptor includes alterations in PAF receptor expression. Transient elevation of cyclic adenosine monophosphate (cAMP) reduces expression of the PAF receptor. This downregulation is accompanied by a decreased responsiveness to a prolonged exposure of PAF. Conversely, priming of macrophages with low levels of LPS can induce a threefold increase in PAF receptor transcript levels, thereby amplifying subsequent response to stimulation.

PAF Receptor Signal Transduction

The wide range of biological responses instigated by PAF receptor activation can be attributed to complicated intracellular signaling mechanisms. Calcium, cAMP, IP_3 , and diacylglycerol (DAG) are all proven second messengers for PAF signaling. **Figure 4** presents an overview of PAF receptor-mediated signaling pathways. Heterotrimeric G proteins are intricately involved in the signal transduction events generated by PAF receptor occupancy. G proteins bind guanine nucleotides, are activated by guanosine triphosphate (GTP), and possess intrinsic GTPase activity. Binding of PAF activates the associated G protein by exchanging GTP for guanosine diphosphate (GDP). The PAF receptor is linked to more than one G protein because some processes are sensitive to pertussis toxin treatment, while

others are resistant. In fact, this G-protein utilization also can differ in different cell types. The activated G proteins, in turn, activate polyphosphoinositide turnover mediated by phospholipase C (PLC). The subsequent generation of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol mobilizes intracellular Ca^{+2} and activates protein kinase C (PKC), respectively. PAF receptor-associated G-protein activation also leads to the activation of cytoplasmic PLA_2 with the subsequent cleavage of arachidonic acid (AA) and the formation of leukotrienes (LT), prostaglandins (PG), and thromboxanes (TX). More recently, investigators demonstrated broader activation of kinases and phospholipases following PAF receptor activation. For instance, PAF receptor activation has been shown to activate mitogen-activated protein kinase (MAPK), PI 3-kinases (PI3K), protein tyrosine kinases, and G-protein receptor kinase.

Experiments in both PAF receptor knockout animals and transgenic animals overexpressing PAF receptors support the pathophysiological role attributed to PAF receptor signaling. Deletion of PAF receptors in mice drastically attenuates systemic anaphylactic responses after antigen challenge, whereas mice overexpressing PAF receptors exhibit hypersensitivity to bacterial endotoxin. It is not surprising then that PAF receptor activation is being investigated as a contributing factor in numerous disease entities including asthma, atherosclerosis, inflammatory bowel disease, ischemia-reperfusion injury, endotoxemia, and allergic disorders.

Glossary

Adaptor A protein linking together proteins that are otherwise unable to interact.

Autocrine signaling A type of signaling in which the cell responds to a stimulus (e.g., growth factor) that is produced by the same cell.

Cell cycle A tightly regulated sequence of events exhibited by dividing cells. It consists of the following phases: Gap 0 (G0, temporary or permanent quiescence); Gap 1 (G1, growth and preparation of the chromosomes for replication); S (synthesis of DNA); Gap 2 (G2, growth and preparation for mitosis); and M (mitosis).

Chemotaxis The ability of cells to migrate toward a gradient of chemoattractant.

Growth factor A substance that needs to be present in the environment of responsive cells in order for them to divide.

Ligand A molecule (or ion) that can interact with a receptor.

Mitogen A substance (e.g., growth factor) that can initiate cell division.

Paracrine signaling A type of signaling in which the cell responds to a stimulus (e.g., growth factor) that is produced by a nearby cell.

Pericytes The pluripotent cells surrounding blood vessels.

Receptor A molecule (mostly of protein nature) able to detect the presence of a specific stimulus (ligand) and give rise to signaling events leading to physiological response(s).

Transphosphorylation A phosphorylation event in which two protein kinases phosphorylate each other (e.g., within the dimer).

Platelet-derived growth factor (PDGF) is a potent mitogen, chemoattractant, and survival factor for cells of mesenchymal origin (such as fibroblasts, smooth muscle cells (SMCs), or glial cells). PDGF exists as a number of isoforms that initiate signaling via two closely related receptor tyrosine kinases (RTKs) named α - and β -receptors. PDGFs and their receptors (PDGFRs) are important for embryonic and postnatal development. Knockout mice lacking either PDGFs or receptors develop severe defects in various tissues and organs, and die before or shortly after birth. In adult organisms, PDGFs participate in wound healing, regulation of blood vessel tone, and maintenance of the interstitial fluid pressure. PDGF signaling is also involved in the pathogenesis of various proliferative diseases (certain tumors, atherosclerosis and restenosis, and fibrotic conditions). PDGFs and their receptors have been best characterized in mammals. However, there is evidence that PDGFR-like proteins are expressed in lower vertebrates, and PDGF-like growth factors have been found in molluscs, annelids, sea urchins (*Lytechinus pictus*), and *Drosophila*. Taken together, these findings indicate that PDGFs and their receptors play an important role in a variety of biological processes throughout eukaryotic species.

PDGF Isoforms

At present, four genes encoding different PDGF chains are known: A, B, C, and D. Biologically active PDGFs exist as disulfide-bonded homodimers designated AA, BB, CC, and DD. A and B chains form a heterodimeric PDGF AB (Figure 1). The history of the discovery of PDGFs dates back as early as 1974, when mitogenic activity of whole blood serum was linked to the presence of platelets. PDGF AB was the first to

be purified and biochemically characterized a few years later, followed by PDGF BB and AA. Cloning of PDGF A and B cDNAs and determination of the structure of corresponding genes were completed in the 1980s.

New members of the PDGF family, PDGF C and PDGF D, were found only recently by searching the database of human-expressed sequences. PDGFs C and D have a two-domain structure with N-terminal CUB domain and C-terminal PDGF/VEGF (core) domain, separated by a hinge region (Figure 1). No heterodimers involving C or D chains have been detected. The unique feature of these two new PDGFs is the requirement for proteolytic cleavage of the CUB domain upon secretion in order to achieve biological activity. Thus, latency may be the reason why these growth factors were not originally detected by functional assays.

PDGF Receptors

PDGFs exert their biological functions by binding to two isoforms of PDGF receptors, α and β , with different degrees of affinity. Both receptors are transmembrane tyrosine kinases, composed of extracellular, transmembrane, and intracellular parts. The extracellular part consists of five immunoglobulin-like domains that are involved in ligand binding (domains I–III) and receptor dimerization (domain IV). The intracellular kinase domain of the PDGF receptors is split into two by ~100-amino acid insert (Figure 1).

PDGF A chain binds specifically to α -receptor, and PDGF B can bind to both α and β . PDGF C was originally described as a ligand for PDGF α -, but not β -receptor; however, it was later shown to bind PDGF β -receptor in cells expressing both α - and β -isoforms. PDGF D has been reported to be a β -receptor

Figure 1 Platelet-derived growth factors and their receptors. PDGFs A and B are synthesized as precursors that are proteolytically processed before secretion. PDGFs C and D are secreted in latent form and activated by proteolytic cleavage of the CUB domain. All PDGF isoforms dimerize prior to the proteolytic cleavage. Specificity of binding of mature active PDGFs to their receptors is shown; dashed arrow indicates the lack of consensus regarding the ability of PDGF DD to cause the formation of a heterodimeric receptor. Domain structure of the PDGF receptor α -subunit (identical to that of β -subunit) is presented. The extracellular part of the receptor consists of five Ig-like domains. PM, plasma membrane; JM, juxtamembrane domain; TK1 and TK2, proximal and distal parts of tyrosine kinase domain; KI, kinase insert; and CT, carboxyl-terminal tail.

ligand, but its ability to bind α -receptor in α/β -expressing cells remains controversial. Interactions of PDGFs with α - and β -receptors are summarized in **Figure 1**. A bivalent dimer, PDGF molecule binds to two receptor subunits causing them to dimerize. Upon dimerization, PDGF receptors become rapidly phosphorylated on multiple tyrosine residues. One of them (regulatory tyrosine) is located in the second part of the kinase domain and is important for receptor kinase activity (Tyr857 in β -receptor and, by homology, Tyr849 in α -receptor). Most of the other phosphorylation sites lie in noncatalytic parts of the receptor (**Figure 2**). The exact sequence of events during receptor activation and formation of signaling complex is unknown. By analogy to other RTKs, it is likely that ligand binding and subsequent dimerization of the receptor induces a conformational change that facilitates transphosphorylation of regulatory tyrosine residues within the dimer. Importantly, the regulatory tyrosine lies within activation loop, the region that is conserved among RTKs. As shown for the insulin receptor, the activation loop blocks the catalytic site in nonphosphorylated receptor, whereas upon ligand-induced phosphorylation it moves away providing access to the substrate. It is possible that the PDGF receptor activation occurs via a similar mechanism, although there is no direct evidence for this in the absence of the crystal structure of PDGF receptors.

Recently, ligand-bound dimerized PDGF β -receptor was found to be less susceptible to dephosphorylation by protein tyrosine phosphatases (PTPs) than the monomeric receptor. It is suggested that this phosphatase protection may contribute to maintenance of the activated (phosphorylated) state of the receptor.

Proteins Associated with the PDGF Receptors and PDGF-Driven Signaling Pathways

A total of 13 tyrosine residues in β -receptor and 11 in α -receptor get phosphorylated upon PDGF stimulation. Phosphorylation of most of the tyrosines within PDGF receptors results in the creation of docking sites for a variety of proteins, many of which in turn get phosphorylated upon association with the receptors (**Figure 2**). These proteins include enzymes (phosphatidylinositol 3'-kinase (PI3-kinase), phospholipase C- γ 1 (PLC γ 1), SH2 domain-containing protein tyrosine phosphatase-2 (SHP-2), GTPase-activating protein of Ras (RasGAP), Src family kinases (SFKs), transcription factors (members of STAT family), or adaptor proteins, such as Grb2, Grb7, Shc, Shb, Nck, or Crk, linking the receptor to signaling proteins further downstream. Some proteins that are recruited to the PDGF receptors are

Figure 2 Intracellular domains of $\alpha\alpha$ and $\beta\beta$ homodimers of the PDGF receptor. Phosphorylated tyrosine residues are shown (dark circles). Numbers indicate their positions in the human PDGF receptor sequence. Association of signaling proteins with phosphorylation sites of the activated PDGF receptors is shown by solid lines (major binding sites) or dashed lines (additional sites). Proteins binding with high affinity (e.g., PI3-kinase, PLC γ 1, and RasGAP) bind to the receptor via one or two phosphotyrosine residues on the receptor, whereas low-affinity binding (e.g., Nck, Shc, or Shb binding to β -receptor) involves multiple sites. Shb was found to bind to most of the phosphorylated tyrosines on the PDGF β -receptor. Fer and LMW-PTP bind to as yet unidentified sites on the PDGF β -receptor.

both adaptors and enzymes, for example, tyrosine phosphatase SHP-2 is able to recruit Grb2 via its phosphorylated C terminus. Association is mediated in most cases by SH2 (Src homology 2) domains of these proteins and is remarkably specific, each phosphorylation site having its own binding partner(s). This specificity is based on the ability of SH2 domains to differentially recognize amino-acid sequence following the phosphorylated tyrosine. Many receptor-binding proteins also contain SH3 (Src homology 3), PTB (phosphotyrosine binding), or PH (pleckstrin homology) domains that may facilitate recruitment of other yet unidentified signaling molecules to the complex.

Cellular Responses Mediated by the PDGF Receptors

Assembly of the PDGF receptor complex initiates a number of signaling pathways leading to cellular responses (Figure 3): chemotaxis, proliferation, differentiation (in certain cell types), and protection from apoptosis. One pathway may lead to several different responses, whereas some of the pathways are redundant and converge on the same cellular effect.

Proliferation

Proliferation is the major and most well-studied cellular effect induced by PDGFs. Virtually all signaling proteins binding to the receptors have been implicated in proliferation, but not all of them have to be present in the signaling complex at the same time to induce the response.

Ras-dependent pathway

The mitogenic pathway that involves Ras, a small GTPase, can be activated through multiple ways in response to PDGF. The complex of Grb2 (adaptor protein) and Sos1 (nucleotide exchange factor for Ras) can bind to the β -receptor either directly or via phosphorylated Shc or SHP-2. This association

brings the complex to the plasma membrane where it activates Ras. Activated Ras GTPase interacts directly with Raf-1 serine/threonine kinase, in turn activating it. Raf-1 is the first kinase in the MAP kinase cascade. Elevation of its activity is followed by sequential activation of MEK and MAP kinases, Erk1 and 2, which are translocated to the nucleus and phosphorylate a number of transcription factors.

As for the PDGF α -receptor, Grb2 is able to bind to it via SHP-2, but there is no evidence of its involvement in Ras activation. Therefore, pathways other than the Ras-mediated one are likely to contribute to α -receptor-mediated proliferation.

The Ras pathway is believed to be counteracted by RasGAP that binds to the PDGF β -receptor (but not to α -receptor) and is able to enhance GTPase activity of Ras, thus converting it from active (GTP-bound) to inactive (GDP-bound) state. The extent to which this negative signaling affects proliferation may depend on many factors (cell type and environmental conditions).

Src

Src (p60^{c-src}) has been shown to be important for PDGF-driven mitogenesis. However, its association with the PDGF receptors and early PDGF-induced elevation of activity are dispensable for proliferative response and may have a different function. Yet, Src is required at multiple time points during PDGF-dependent cell-cycle progression. Thus, elevation of Src activity early in G1 leads to increase of *c-myc* expression, which is required for transition through G1. Importance of Src has also been confirmed for late G1 and for the exit from M-phase of the cell cycle.

PLC γ 1

PLC γ 1 binds to the PDGF receptors upon ligand stimulation and becomes phosphorylated and activated. Increasing the catalytic activity of PLC γ 1 leads to production of inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG). IP3 is involved in regulation of cytoplasmic Ca²⁺ levels, which,

Figure 3 Major events initiated by the PDGF β -receptor and culminating in biological responses. Upon ligand binding, activated PDGF β -receptor recruits enzymes and adaptor proteins that start a number of distinct signaling pathways, some of which are shown on the figure. Note that not all of them are initiated by the same receptor dimer or in the same cell. Arrows represent either physical or functional interactions along the pathways. The least defined part of the signaling cascade is the one that bridges the receptor-proximal events with proteins that carry out cellular responses. PDGF is necessary but not sufficient to achieve biological effects. In a living organism, other growth factors and hormones, as well as cell–cell and cell–matrix interactions within tissues and organs make indispensable contributions.

together with direct action of DAG, can contribute to activation of certain members of the PKC family. In particular, DAG has been shown to activate protein kinase C- ζ (PKC- ζ), which then activates Raf-1 and, consequently, the rest of the MAP kinase cascade, leading to proliferation. PLC γ 1 is involved in PDGF-stimulated proliferation mediated by β -receptor, whereas in the case of α -receptor, it is important mostly for the motility response.

PI3-kinase

PDGF-dependent PI3-kinase activation is critical for mitogenesis in most cell types. Prolonged exposure to PDGF, needed to induce cell-cycle progression in quiescent cells, causes two distinct peaks of PI3-kinase activity, one within minutes and another following a delay of several hours. Only the second peak was found to be important for the cell-cycle progression,

whereas the early increase of activity is required only for immediate responses to PDGF, such as chemotaxis.

How this biphasic increase of PI3-kinase activity is linked to the cell-cycle machinery still remains an open question. Continuous treatment with PDGF can be substituted by two separate pulses of the growth factor, the first getting cells out of G0 to early G1 and the second pushing them through late G1 and into S phase. Early elevation of *c-myc* and sustained activation of the MAP kinase pathway can replace the first pulse of PDGF, but is not sufficient to drive the cell through late G1. To complete cell-cycle progression, a properly timed second peak of PI3-kinase activity (second pulse of PDGF or just the addition of PI3-kinase lipid products) is required. It is hypothesized that early *c-myc* and Erk activation triggers expression of new protein(s) whose interaction with the late PI3-kinase products is critical for S phase entry.

Chemotaxis

Most receptor-expressing cells exhibit chemotaxis upon exposure to PDGF. Migration of pericytes in response to SMC-released PDGF plays a critical role in capillary formation, which is particularly important during embryonic development. In the process of wound healing, PDGF causes chemotaxis of neutrophils and macrophages, as well as fibroblasts and SMCs.

α - and β -PDGF receptors differ in their ability to mediate chemotaxis. PDGF β -receptor homodimer as well as α - β heterodimer potently stimulate it. However, the ability of α - α homodimer to drive chemotaxis remains controversial and may depend on the cell type. This difference may be explained by variations in composition of the signaling complex assembled by different receptor dimers, which may be cell-type specific.

PI3-kinase and Ras pathways

Chemotaxis involves dynamic remodeling of cytoskeleton, including rearrangement of actin filaments and microtubules, changes of focal adhesions, and formation of lamellipodia or filopodia. These processes are controlled, in part, by the Rho family of small GTPases (RhoA, Rac1, and Cdc42), which are activated by the PDGF receptors via different pathways. The PI3-kinase pathway is considered to be the major one. Activation of the Rho family of small GTPases is dependent on PI3-kinase lipid products. The Ras pathway that can be initiated by the PDGF receptor independently from PI3-kinase pathway, leads to chemotactic response via activation of Rac1, another small GTPase Ral, and in some cell types, MEK1 and stress-activated kinase p38. Interestingly, PI3-kinase is able to interact directly with Ras and activate it, whereas both Ras and Rho family GTPases can activate PI3-kinase, forming a positive feedback loop. Thus, reciprocal regulation of Ras and PI3-kinase provides an example of interaction between different PDGF-dependent pathways.

RasGAP, a negative regulator of Ras, has been shown to inhibit chemotaxis. However, in some cell types, RasGAP has also been shown to have a positive impact on motility that is most likely independent from Ras.

PLC γ 1

PLC γ 1 promotes chemotaxis in many cell types, but the knowledge about what happens downstream of PLC γ 1 is only starting to emerge. Upon PDGF stimulation, PLC γ 1 activates sphingosine kinase through IP₃ formation and subsequent release of Ca²⁺ from intracellular stores. Sphingosine kinase product, sphingosine-1-phosphate (SPP), is a ligand for EDG-1, a G-protein-coupled receptor (GPCR). Stimulation of EDG-1 by SPP leads to activation of Rho family GTPases, which, in turn, results in remodeling of actin cytoskeleton and cell-matrix adhesion sites. This is a new example of receptor crosstalk, where an RTK requires activation of a GPCR to achieve a cellular response.

PKC isoforms that are activated via both PI3-kinase and PLC γ 1 pathways are also involved in chemotactic signaling, as chemotaxis is reduced when PKCs are inhibited or downregulated.

SHP-2 and low-molecular-weight phosphatase

Two other positive mediators of PDGF-induced chemotaxis are tyrosine phosphatases SHP-2 and low-molecular-weight

phosphatase (LMW-PTP), both directly associated with the phosphorylated PDGF receptor and activated by PDGF-dependent phosphorylation. Involvement of SHP-2 in chemotactic signaling may occur via the Ras pathway, since SHP-2 can serve as an adaptor protein for Ras binding. LMW-PTP is likely to act through dephosphorylating and inactivating one of its cellular targets, p190RhoGAP, a negative regulator of Rho GTPase, thus leading to increased activation of Rho and subsequent cytoskeletal rearrangements.

SFKs

The role of SFKs in PDGF-induced chemotaxis is not clear. A pathway leading to chemotaxis is initiated at SFK-binding sites in the juxtamembrane domain of the PDGF α -receptor, since mutating these tyrosines to phenylalanine residues results in chemotaxis inhibition. However, it is not yet clear whether it is SFKs or other signal transduction molecules binding to the same sites that are responsible for cell migration, since in triple SFK knockout cells, PDGF-AA-dependent cell migration is intact.

It is necessary to note that $\alpha\alpha$ - and $\beta\beta$ -homodimers of the PDGF receptor cause different, although partially overlapping, cellular responses, due to the differences in their ability to bind signaling proteins (Figure 2). For instance, α -receptor homodimer has been found to send a less potent mitogenic signal than the β -receptor homodimer. Additionally, in some cell types (SMC, human foreskin fibroblasts), it fails to mediate a chemotactic response to PDGF AA and inhibits chemotaxis induced by other agents. PDGF β -receptor homodimer formation generally results in higher mitogenicity and chemotaxis. The heterodimeric α - β receptor is believed to have unique signaling properties, due to the altered phosphorylation pattern of both α - and β -subunits, which results in recruitment of a different subset of signaling proteins. In particular, the heterodimer mediates a stronger mitogenic response than either α - α or β - β complexes do. Distinct signaling properties of different PDGF receptor dimers are based not only on different intrinsic properties of receptor isoforms, but also on the type of cells where these receptors are expressed and on varying experimental conditions.

Negative Regulation of the PDGFR Signaling

Down-regulation mechanisms described for the PDGFR include internalization, ubiquitin-mediated proteolysis (degradation), and dephosphorylation by PTPs. Their relative contribution to the termination of signaling appears to be different.

Internalization and Degradation

Internalization of the PDGF receptors, mediated by clathrin-coated pits, occurs shortly after ligand stimulation and is dependent on the receptor kinase activity. Intracellular trafficking of the PDGF β -receptor involves PI3-kinase, but is not entirely elucidated yet. Internalized receptors can be recycled and go back to the cell surface or can be directed to lysosomal degradation, which actually results in receptor downregulation. However, before they are degraded, internalized receptors remain associated with downstream proteins and continue to signal. For this reason, internalization and subsequent

trafficking can be considered a late signaling stage rather than merely the method of receptor inactivation.

Additionally, PDGFRs can be targeted for cytoplasmic degradation in proteasomes via polyubiquitination. Ubiquitination of the receptors occurs upon ligand binding and is strictly dependent on receptor autophosphorylation. Generally, multi-ubiquitin chain is added to proteins by E3–E2 ubiquitin ligase system and after that ubiquitinated proteins are recognized by the 26S proteasome and degraded. c-Cbl, a E3 ubiquitin ligase, has been shown to be phosphorylated upon PDGF stimulation and is therefore likely to contribute to the PDGFR ubiquitination and subsequent proteolysis. Proteolytic degradation can be considered a true mechanism of receptor downregulation that terminates signaling through decreasing the number of the PDGF receptor molecules.

Dephosphorylation by PTPs

PTP-dependent dephosphorylation of the PDGF receptors represents another level of regulation of PDGF-induced signaling. Thus, dephosphorylation of the regulatory site or nonspecific removal of phosphate from all tyrosine residues would shut down all signaling, whereas site-specific dephosphorylation would selectively block corresponding signaling pathways. LMW-PTP, for instance, has been shown to act both ways. This PTP selectively interferes with two pathways initiated by the PDGF β -receptor: Src-dependent induction of *c-myc* and STAT1/3-mediated *c-fos* expression. It can also affect kinase activity of the PDGF β -receptor by dephosphorylating Tyr857, providing a general negative regulation of all downstream signals.

Unlike LMW-PTP that acts on membrane-bound PDGF β -receptor, PTP1B was found to dephosphorylate the receptor upon its internalization on the surface of the endoplasmic reticulum, shutting down signaling at a later time point, yet before the receptor gets degraded or recycled to the plasma membrane.

The ability of SHP-2 to act as both positive and negative regulator of PDGFR signaling puts it apart from other receptor-directed PTPs. It is able to dephosphorylate selectively, tyrosines 771 and 751 on the β -receptor, potentially turning off RasGAP and PI3-kinase pathways. On the other hand, SHP-2 can serve as an adaptor for Grb2 binding, therefore initiating Ras-mediated signaling. Additionally, SHP-2 has been implicated as a positive regulator in the stimulatory effect of integrins on PDGF receptor signaling.

An increase of intracellular reactive oxygen species (ROS) is an early PDGF-dependent event mediated by PI3-kinase and Rac1, and it was shown to be important for mitogenic signaling. Since ROS reversibly inhibits PTPs, it is likely that this event helps to prevent the negative effect of PTPs during early stages of PDGF signaling.

Developmental Role of the PDGF Receptors

At very early stages of embryonic development (before gastrulation), both PDGF α -receptors and PDGF A chain are expressed throughout the embryo, suggesting that PDGF AA

may be acting in an autocrine manner to stimulate cell proliferation. At later stages, PDGF β -receptor and PDGF B chain appear, and both receptors and growth factor chains start to show a distinct expression pattern. The expression of PDGF C largely overlaps with that of PDGF A, and information about PDGF D expression in embryo is still incomplete. PDGF receptors are found mainly in cells of mesodermal origin, with some exceptions (e.g., central nervous system), whereas PDGFs are present in adjacent ecto- and endodermal derivatives. This distribution indicates that, during morphogenesis, PDGFs act in a paracrine manner to induce migration of receptor-expressing mesenchymal cells.

As shown by genetic analysis in mice, interruption of PDGF signaling leads to morphogenic defects and embryonic or perinatal lethality. PDGFR α -null mice die before birth, many (but not all) at a very early stage. Those available for analysis have myotomal abnormalities, rib fusions, defects in neural crest derivatives, and incomplete cephalic closure. PDGF A knockouts demonstrate an emphysema-like lung condition characterized by the absence of mature alveoli. This defect originates due to a lack of migration of PDGF α -receptor expressing alveolar SMC progenitors in the walls of alveolar sacs. Both PDGF A and PDGFR α -null mice also display hypoplasia of skin mesenchyme and abnormal intestinal villi formation. The most pronounced phenotypic features of the PDGF B and PDGF β -receptor knockout mice are defects in kidney glomeruli and capillary microaneurisms. Both result from failure of capillary branching and dilation of capillary walls in the absence of PDGF-dependent recruitment of pericytes and kidney mesangial cells. Other abnormalities include dilation of heart and large arteries, thrombocytopenia, and anemia.

Glossary

Chelation The removal of free metal ions from solution by an organic chemical.

Herbicide Chemical agent used to curtail plant growth.

Plastid Generic name for chloroplasts and chloroplast precursors.

Singlet oxygen A reactive oxygen radical with a single unpaired electron.

Introduction

Porphyrins are cyclic tetrapyrroles that perform critical roles in a variety of biological systems. Examples of important tetrapyrroles include heme, siroheme, and heme d₁ (all with chelated iron), chlorophyll (with chelated magnesium), coenzyme B₁₂ (which possesses only three meso carbons between pyrrole rings, is a corrin rather than a porphyrin, and contains chelated cobalt), and factor F₄₃₀ (with chelated nickel). Heme, as a prosthetic group in various hemoproteins, is necessary for oxygen transport and storage as part of hemoglobin and myoglobin. It is essential for electron transport as part of various cytochromes and is also required by mixed function oxidases as a part of cytochrome P₄₅₀. In addition, heme is needed for the decomposition and production of hydrogen peroxide as a cofactor of catalase and peroxidase, respectively. Recently, heme has been shown to play a regulatory role in several central cellular processes, including transcription, translation, and intermediary metabolism. Heme d₁ is a cofactor in dissimilatory nitrite reductase, while siroheme serves as the cofactor in both assimilatory nitrite and sulfite reductases. Neither heme d₁ nor siroheme is synthesized by mammals.

Several types of chlorophylls exist which differ with respect to the substituents on the tetrapyrrole ring. Chlorophylls are employed by photosynthetic organisms to absorb energy for photosynthesis. This process harnesses the vast majority of energy consumed by living organisms and only chemolithotrophic bacteria are independent of this energy source. Chlorophylls are required in the first stage of photosynthesis, whereby visible radiation excites an electron in the porphyrin that, upon returning to a lower energy state, provides the energy needed for the synthesis of adenosine triphosphate (ATP) and nicotinamide adenine dinucleotide phosphate (NADPH).

Coenzyme B₁₂ consists of cobalamin (vitamin B₁₂), a corrin ring, which is linked to dimethylbenzimidazole and 5' deoxyadenosine via its central cobalt atom. The bond between the cobalt and the latter substituent is a weak cobalt–carbon bond, the only example known in biology, which catalyzes intramolecular rearrangements by cleaving homolytically to generate a free radical. Examples include methylations in methionine synthesis and the reduction of ribonucleotides to deoxyribonucleotides. Finally, there is a nickel(II) tetrapyrrole, factor F₄₃₀, which is found in methanogenic bacteria and is involved in methane metabolism.

Biosynthesis of Porphyrins

Figure 1 illustrates the first three steps of tetrapyrrole biosynthesis which are common to all the tetrapyrroles mentioned above. All of these molecules have a core structure of four pyrrole rings, designated A–D, as shown on the structure of heme in Figure 1. The carbon atoms are numbered 1–20 starting in ring A and ascending in a clockwise direction around the perimeter of the porphyrin ring.

Formation of δ -Aminolevulinic Acid

The first common intermediate in tetrapyrrole biosynthesis is δ -aminolevulinic acid (ALA). Two pathways for its synthesis are found in nature: the C₄ pathway in animals, fungi, and some bacteria (α -group of proteobacteria) including *Rhodospirillum rubrum*, and the C₅ pathway in plants, algae, archaea, and most other bacteria including cyanobacteria. In the C₄, or Shemin pathway, ALA is formed by the condensation of glycine and succinyl coenzyme A (CoA) in a reaction catalyzed by the enzyme ALA synthase (ALAS). In the C₅ pathway an NADPH-dependent glutamyl-transfer RNA (tRNA) reductase produces glutamate 1-semialdehyde (GSA) from glutamyl-tRNA, which is subsequently converted to ALA by the replacement of the aldehyde moiety with an amide group. The C₅ pathway is thought to be ancestral to the Shemin pathway as bacteria with the former lack the α -ketoglutarate–dehydrogenase complex to make succinyl CoA. This group includes cyanobacteria such as *Synechocystis*, which may explain why plants today retain the C₅ pathway.

ALA to Uroporphyrinogen III

In all organisms studied to date, the conversion of ALA to uroporphyrinogen III proceeds via exactly the same steps. This process is summarized in Figure 1. The first step involves the condensation of two ALA molecules to form porphobilinogen with the release of two molecules of H₂O. This reaction is catalyzed by porphobilinogen synthase, also known as ALA dehydratase. Hydroxymethylbilane synthase, also known as porphobilinogen deaminase, catalyzes the condensation of four molecules of porphobilinogen in the order A, B, C, and D (the letters representing the rings of the ultimate tetrapyrrole product).

Figure 1 The porphyrins. The first three steps common to all porphyrin biosynthesis and the ultimate products of this branched metabolic pathway.

This condensation gives rise to the first linear tetrapyrrole, hydroxymethylbilane, also known as preuroporphyrinogen.

The enzyme hydroxymethylbilane synthase synthesizes its product by building on a dipyrromethane cofactor (a modified dipyrrole) which is posttranslationally attached to a cysteine residue of the enzyme. The first porphobilinogen molecule condenses with the cofactor and further porphobilinogen molecules are subsequently added in a head-to-tail fashion to form hydroxymethylbilane. The enzymatic formation of the first macrocyclic tetrapyrrole, uroporphyrinogen III, is catalyzed by the enzyme uroporphyrinogen III synthase. During this reaction, the D pyrrole ring of hydroxymethylbilane undergoes an inversion via a spiro intermediate. As free hydroxymethylbilane spontaneously reacts to form the biologically inactive isomer, uroporphyrinogen I, the enzyme must be present during or immediately after the release of hydroxymethylbilane from hydroxymethylbilane synthase to ensure that the correct isomer, uroporphyrinogen III, is formed.

Heme and Chlorophyll Biosynthesis

The biosynthesis of heme and chlorophyll proceeds along a common pathway until a branch point is reached at protoporphyrin IX (Figure 2). The formation of protoporphyrin IX from uroporphyrinogen III is achieved via a series of decarboxylation and oxidation steps. Uroporphyrinogen decarboxylase catalyzes the removal of a carboxyl group from each pyrrole ring to form coproporphyrinogen III. This is converted to protoporphyrinogen IX via the action of two enzymes, coproporphyrinogen oxidase and protoporphyrinogen oxidase. During aerobic growth both enzymes use oxygen as the terminal

Figure 2 Heme and chlorophyll biosynthesis. The branching of the heme and chlorophyll biosynthetic pathways. The enzymes that catalyze the individual steps are shown in blue.

electron acceptor. However, anaerobic organisms have been shown to possess oxygen-independent isozymes and some facultative anaerobes encode both types of coproporphyrinogen oxidase. The pathway, as described above, is conserved for almost all organisms studied, except *Desulfobrio vulgaris* and *Methanosarcina barkeri*, in which protoheme is formed from uroporphyrinogen III indirectly via precorrin-2.

The next step involves the insertion of a divalent cation into the porphyrin ring. Ferrochelatase catalyzes the insertion of an iron(II) ion while magnesium chelatase, as its name suggests, catalyzes the insertion of a magnesium(II) ion. Ferrochelatase distorts the porphyrin ring slightly to allow for proton abstraction and iron(II) insertion. The insertion of magnesium requires the presence of MgATP and the participation of all three subunits of the heterotrimeric magnesium chelatase.

Subsequent steps of the chlorophyll biosynthetic pathway involve methylation and cyclization of the propionate group on ring C. After the reduction of the vinyl group on ring C, a light-dependent reaction takes place. This is catalyzed by protochlorophyllide reductase (POR) and is one of the only two reactions known to be light dependent, the other being catalyzed by DNA photolyase. This reaction can also proceed via a light-independent reaction, catalyzed by dark POR (DPOR). The formation of chlorophylls requires the addition of a hydrophobic tail to the propionate group on ring D via an esterification reaction. In the cases of chlorophyll and bacteriochlorophyll, these long-chain alcohols are phytol and geranylgeraniol, respectively.

Coenzyme B₁₂, Siroheme, Heme d₁, and Factor F₄₃₀ Biosynthesis

Figure 3 summarizes the synthesis of coenzyme B₁₂, siroheme, heme d₁, and factor F₄₃₀ from uroporphyrinogen III. The first step in synthesis of any of these porphyrins involves the methylation of uroporphyrinogen on rings A and B to form precorrin-2. Reduction to form sirohydrochlorin and subsequent ferrochelation yields siroheme, the prosthetic group for both nitrite and sulfite reductases. Factor F₄₃₀ synthesis requires the cyclization of substituents on rings B and D and the chelation of nickel(II), which is bound to the pyrrole nitrogen on ring C. This final step is thought to be catalyzed by an ATP-dependent nickel chelatase. The steps involved in the synthesis of heme d₁ are not yet known beyond the formation of precorrin-2.

The formation of corrin coenzyme B₁₂ involves a branched pathway consisting of several reactions. Figure 3 shows that the synthesis of cob(II)yrinate a,c-diamide can occur by either

Figure 3 Coenzyme B₁₂, siroheme, heme d₁, and factor F₄₃₀ biosynthesis.

an anaerobic or an aerobic pathway. Both pathways involve the methylation, reduction, and isomerization of precorrin-2, along with the insertion of a central cobalt atom. The anaerobic chelatase has been compared to ferrochelatase as it is encoded by a single gene and does not require MgATP. The aerobic cobalt chelatase is similar to the magnesium chelatase involved in chlorophyll biosynthesis, as it is heterotrimeric and requires MgATP for catalysis. Subsequent formation of coenzyme B₁₂ proceeds via alkylations, phosphorylation, an internal rearrangement, and the coordination of an adenosyl group to the central cobalt atom.

Regulation

As δ -ALA is the universal precursor for porphyrin synthesis, the supply of this metabolic intermediate ultimately governs whether or not porphyrin synthesis may take place. However, there are several examples where other points in the pathway are subject to regulation. Heme plays a key role as a cofactor for many redox reactions in several different cell types and requires iron as a cofactor. From this, it is clear that the regulation of heme biosynthesis must be dealt with on a global scale among different cell types and subcellular compartments. The model of negative feedback regulation mediated by a single regulator (heme) at a single site (ALAS) remained dogma for many years. Only after compelling evidence was generated to support regulation at other sites was it accepted that heme biosynthesis is subject to more complex control.

In plants multiple tetrapyrroles are produced including heme, chlorophyll, and siroheme. Regulation of these cofactors along with the proteins that bind them is critical due to their reactive nature. Main control points in plants include the formation of δ -ALA, the metal chelation reactions, and steps in siroheme synthesis. The biosynthesis and regulation of heme d₁, cofactor B₁₂, and factor F₄₃₀ are more poorly understood. As mammals do not synthesize these cofactors, little work has been performed on the regulation of these pathways.

Regulation of Heme Biosynthesis

Role of ALAS

In animal cells two ALAS genes exist that are classified by their cellular localization. ALAS-E (erythroid; or ALAS-2) is induced during erythroid differentiation and ALAS-1 encodes ALAS in other tissues. ALAS-1 is also referred to as ALAS-H (housekeeping) or ALAS-N (nonerythroid). The primary sequence of both ALAS proteins is highly conserved. However, significant differences exist between the regulatory regions of the genes and the untranslated regions of their respective messenger RNAs (mRNAs), which are manifested in the tissue-specific expression of the two enzymes.

Regulation at sites other than ALAS

Although it is accepted that ALAS is the major site of regulation, several examples of pathway control exist at the level of gene expression. In mammals, all the genes that encode heme biosynthetic enzymes possess both housekeeping- and erythroid-specific promoter elements, although only ALAS is represented by two distinct genes.

Several examples of regulation of enzymes found later in the heme biosynthetic pathway have been identified. A good example of regulation in response to an external stimulus is exhibited by the coproporphyrinogen oxidase of the nitrogen-fixing bacterium *Azorhizobium caulinodans*. The enzyme responsible for nitrogen fixation, nitrogenase, requires the absence of oxygen to convert dinitrogen into ammonia. This organism is thought to possess both aerobic and anaerobic coproporphyrinogen oxidases and switches to the anaerobic isozyme in response to falling oxygen levels. Regulation of the antepenultimate enzyme in heme biosynthesis by the electron transport chain is seen in *Escherichia coli*. In this organism a respiratory electron transport chain component has been shown to act as the electron acceptor for protoporphyrinogen oxidase. This reaction is catalyzed by an enzyme distinct from the oxygen-dependent protoporphyrinogen oxidase.

Deficiencies in Porphyrin Synthesis

Porphyrias

Porphyrias are inherited diseases caused by point mutations or deletions in the genes encoding heme biosynthetic enzymes. Individuals with these disorders are usually able to synthesize normal amounts of heme, but accumulate pathway intermediates which cause the clinical symptoms of porphyria. These diseases can be divided into three groups: (1) cutaneous porphyrias, characterized by photosensitization; (2) acute porphyrias, where individuals experience abdominal pain, psychiatric disorders, constipation, vomiting, and paralysis; and (3) mixed porphyrias, which manifest themselves as a combination of both. Figure 4 illustrates the porphyrias that result from deficiencies in specific steps of the pathway.

Herbicides

The porphyrin biosynthetic pathway has been targeted for inhibition by certain herbicides to curtail the production of chlorophyll. Diphenyl ether-type herbicides, acifluorfen in particular, have been shown to act as potent inhibitors of protoporphyrinogen oxidase, the last enzyme before the branchpoint of heme and chlorophyll biosynthesis. These molecules compete for the tetrapyrrole-binding site on the enzyme, which impedes the binding of protoporphyrinogen. Hence, protoporphyrin production is inhibited, leading to reduced levels of heme and chlorophyll. As a result, plants treated with such herbicides appear chlorotic (yellow colored) due to their ability to produce carotenoids but not chlorophylls. The action of these herbicides is characterized by the accumulation of protoporphyrinogen IX. This diffuses out of the plastids/mitochondria and is oxidized to protoporphyrin IX via nonspecific plant peroxidases. This mislocation of protoporphyrin IX leads to phototoxicity through the evolution of singlet oxygen species.

Porphyryn Catabolism

Much of the work on porphyrin catabolism has focused on heme and chlorophyll degradation in both prokaryotes

Figure 4 The porphyrias. The porphyric disorders which result from deficiencies in specific steps of the heme biosynthetic pathway are shown in blue.

and eukaryotes. While the role of chlorophyll catabolism appears mainly for the recovery of Mg and macrocycle degradation, heme catabolism serves multiple purposes. Many pathogenic prokaryotic organisms sequester exogenous heme and catabolize this as a source of iron to fulfill their metabolic needs. In plants and cyanobacteria, the heme macrocycle is cut open releasing the iron and the linear tetrapyrrole is used to make the light-harvesting pigments phycobilins and phytychromobilins.

In the metazoans heme catabolism serves not only to degrade heme, but also to form compounds that serve other purposes. The main source of heme for catabolism in higher animals, including man, is senescent erythrocytes that liberate large amounts of hemoglobin during hemolysis. Catabolism of heme is needed for iron recycling, as well as for the degradation of a potentially harmful molecule. In nonplacental animals heme is catabolized to the water-soluble compound biliverdin, but in placental animals, biliverdin is converted to the poorly soluble bilirubin. Bilirubin in mammals is glycosylated, thereby making it soluble. This conjugated bilirubin is then excreted via the kidney. Inability to excrete bilirubin may result in the disease states called hyperbilirubinemias. In premature neonates which lack the glycosylating enzyme this may result in kernicterus. Three inherited disorders of bilirubin excretion are Gilberts syndrome, and Crigler–Najjar syndrome type I and II.

The catabolic reactions are catalyzed by the action of two enzymes: heme oxygenase and biliverdin IX α reductase. The products of these reactions are the physiologically important compounds bilirubin, which at an appropriate concentration and body location can serve as an effective antioxidant

Figure 5 Heme catabolism. The conversion of heme to bilirubin. The enzymes that catalyze each step are shown in italics in blue.

and carbon monoxide, a neuronal messenger. Heme catabolism is the only reaction in mammals that produces carbon monoxide. **Figure 5** shows the degradation of heme to bilirubin IX α . The catabolites of heme degradation biliverdin IX α and bilirubin IX α are colored compounds, green and yellow, respectively, accounting for the color progression observed in a healing hematoma.

Interestingly, chlorophyll catabolism, for the most part, produces colorless and nonfluorescent products. Similar to what is seen in heme degradation by heme oxygenase, the key step in chlorophyll degradation appears to be an oxygenolytic cleavage of the porphyrin macrocycle between rings A and B (see [Figure 1](#)). The enzyme responsible for this reaction has yet to be identified as having the role(s) of any of the catabolites. Little is known in terms of the degradation of other porphyrins.

Potassium Channels in the Inner Membrane of Mitochondria in Various Organisms: From Unicellular Eukaryotes to Higher Plants and Mammals

I Szabó and M Zoratti, University of Padua, Padua, Italy

© 2013 Elsevier Inc. All rights reserved.

Glossary

Conductance (G) The ratio between the electric current and the applied voltage. The conductance is expressed in siemens ($S = \text{ampere/volt (A/V)}$).

Electrochemical proton gradient An electrochemical gradient has two components: (1) the electrical component is caused by a charge difference across the lipid membrane ($\Delta\Psi$) and (2) a chemical component is caused by a differential concentration of ions across the membrane (ΔpH). The combination of these two factors determines the thermodynamically favorable direction for an ion movement across a membrane. It is commonly expressed in

millivolts (mV) and in mitochondria its value corresponds to $-180/-200$ mV (negative on matrix side).

Electrophysiology Comprises various methodologies to study the electrical properties of biological membranes in organelles, cells, and tissues. It involves measurements of voltage change or electric current on a wide variety of scales from single ion channel proteins to whole organs.

Mitoplasts Swollen mitochondria with only remnants of the outer membrane are present and the mitoplasts thus become suitable for electrophysiological patch clamp experiments.

Mitochondria are bioenergetic adenosine triphosphate (ATP)-producing organelles of endosymbiotic origin, formed by an outer membrane, permeable to metabolites and ions, an inner membrane (IMM), where oxidative phosphorylation takes place, an intermembrane (periplasmic) space, and the matrix, enclosed by the IMM, where important metabolic processes such as the citric acid cycle and fatty acid beta-oxidation occur. The mitochondrial inner membrane has long been considered to be poorly permeable to cations and anions, since the strict control of inner mitochondrial membrane permeability is crucial for efficient ATP synthesis. Over the past 30 years, however, it has become clear that various ion channels are present in the IMM along with well-characterized carriers (antiporters and uniporters). Ion channels can transport up to 10^7 ions per second, and the electrochemical driving forces for ion movement across the IMM are of considerable magnitude, given the very high negative membrane potential across this membrane (in energized mitochondria $\Delta\Psi_m$ is around -180 mV) created by the respiration-driven efflux of protons from the matrix during oxidative phosphorylation. Channel proteins therefore are expected to be present in extremely low abundance and/or to be open for very short times to maintain the low permeability to ions required to exploit the proton motive force for ATP generation. Nonetheless, these channels are crucial to the mechanism of energy supply and are a decisive factor in determining whether a cell lives or dies. In fact, increased mitochondrial membrane permeability due to activation of mitochondrial megachannel/permeability transition pore (PTP) is a hallmark of cell death. Mitochondrial ion channels for Ca^{2+} , K^+ , or anions have been functionally and pharmacologically characterized at the single-channel level, not only in isolated mitochondria but also in intact mitochondria, in intact cells, and in some cases at whole-organ level.

Potassium fluxes (the K^+ cycle) can be monitored by classical bioenergetic techniques. These include mitochondrial swelling assays (since net uptake of K^+ salts will be

accompanied by osmotically obligated water, resulting in matrix swelling), measurements of changes in mitochondrial redox potential, respiration, and transmembrane potential, and direct determination of K^+ uptake into mitochondria using potassium-selective electrodes. Furthermore, pathways allowing potassium flux can be revealed directly by patch-clamp measurements on swollen mitochondria (mitoplasts) conserving only remnants of the outer membrane or by electrophysiological planar lipid bilayer recordings of channels in proteoliposomes containing mitochondrial membrane proteins.

The Mitochondrial Potassium Cycle

By using these methods, it was established that electrogenic proton ejection by the respiratory chain generates a high negative electrical membrane potential, which drives electrophoretic K^+ influx through potassium-selective ion channels. The ones that have been identified so far are listed below and are shown in [Figure 1](#). K^+ is the major monovalent cation in the cytoplasm and is consequently an important ion mediating changes in volume when the K^+ conductance of the inner membrane is altered. As mentioned above, net uptake of K^+ salts will be accompanied by water, resulting in matrix swelling. Excess matrix K^+ is then ejected by the electroneutral K^+/H^+ antiporter which is regulated to sense volume changes and uses the energy stored in the proton gradient to expel K^+ . A continuous electrophoretic influx of cations followed by their release via an electroneutral mechanism would result in a futile cycle dissipating the membrane potential. Respiring mitochondria in potassium chloride media undergo massive swelling upon addition of the potassium ionophore valinomycin (which allows the rapid electrophoretic uptake of K^+). Simultaneous addition of excess nigericin (which promotes the electroneutral exchange of H^+ and K^+) does prevent swelling but causes permanent uncoupling (where electron

Figure 1 Potassium channels in the inner mitochondrial membrane. Two calcium-activated channels (BKCa and IKCa), two-pore potassium channel TASK-3, an ATP-inhibited channel (KATP), and Kv1.3, which can be blocked by a lysine residue (K128) of outer-membrane-inserted Bax molecule, are shown. In the outer membrane, the voltage-gated anion channel, VDAC, is indicated.

transport through components of the respiratory chain is not coupled to ATP production). In intact mitochondria, energy dissipation is limited by the fact that channels and electrophoretic uptake pathways (uniports) are tightly regulated. The K^+ cycle thus can potentially modulate the tightness of coupling between respiration and ATP synthesis in mitochondria, thereby maintaining a balance between energy supply and demand in the cell. It also ensures mitochondrial volume regulation, preventing excessive matrix swelling, thus maintaining the structural integrity of the organelle, or contraction, which would inhibit respiration. Finally, the K^+ cycle seems to regulate mitochondrial reactive oxygen species (ROS) production. This process is not yet completely understood. Some experimental results suggest that depolarization of the IMM and increase of the respiratory rate induced by opening of a K^+ channel may increase the leak of electrons from the respiratory chain to form superoxide anion, that is, ROS. On the other hand, activation of potassium channels has also been reported to reduce ROS production. Both effects might take place, depending on the tissue under consideration.

The Mitochondrial ATP-Dependent Potassium Channel

An ATP-sensitive potassium channel has been described in mitochondria of various tissues in mammals as well as in unicellular organisms and in plant mitochondria and has been proposed to correspond to the well-studied potassium uniport. The channel is selective for K^+ over Na^+ and in the presence of Mg^{2+} it is inhibited by ATP added to the cytoplasmic side of the IMM. The ATP-inhibited channel can be reactivated by the plasma membrane KATP channel openers, cromakalim and diazoxide, the latter being much more potent with the mitochondrial than the plasma membrane channel. Other inducers of mitoKATP activity include ROS, guanosine triphosphate (GTP), guanosine diphosphate (GDP), and uridine diphosphate (UDP), while in

addition to ATP and adenosine diphosphate (ADP), NO, quinine, 5-hydroxydecanoic acid, glybenclamide, palmitoyl-CoA, and oleyl-CoA inhibit mitoKATP.

The detailed pharmacological characterization, initially performed mainly on rat liver mitochondria, later allowed determination of the presence of mitoKATP in various organisms. In the nonphotosynthesising free-living amoeboid protist (*Amoebozoia*), *Acanthamoeba castellanii*, the electrophysiological (single-channel properties of the channel reconstituted into planar lipid membrane) and pharmacological (effect of specific modulators on bioenergetics of isolated mitochondria) profiles of the mitoKATP channel display similarities to mammalian plasma membrane ATP-sensitive K^+ channels (KATP channels). Swelling experiments have been used to assess the effects of some of the above-mentioned substances, known to modulate the mammalian mitoKATP channel, on mitochondria of protozoan parasites trypanosomatids, *Trypanosoma cruzi* (which causes Chagas' disease) and *Crithidia fasciculata*. MitoKATP activity was identified also in mitochondria of the nematode worm *Caenorhabditis elegans*. In higher organisms, mitoKATP channel activity, revealed by electrophysiology or classical bioenergetic techniques, is present in mitochondria of liver, heart, brain, kidney, skeletal muscle, and human T lymphocytes. Furthermore, in plant mitochondria, which possess a very active K^+ cycle, a K^+ uniport pathway with characteristics of mitoKATP has been observed to sustain an ion flow sufficient to uncouple respiration. Very recently, the first patch-clamp experiments on plant mitochondria identified mitoKATP also at the level of single-channel activity.

Concerning the molecular identity of mitoKATP, a definitive identification is not yet available. As for its plasma-membrane-located counterpart (KATP channel), inward rectifying potassium channel subunits (Kir6.1 or Kir6.2), together with the regulatory subunit sulfonylurea receptor (SUR), have been proposed to give rise to mitoKATP activity. A comparative genomics/proteomics approach may help molecular identification in view of the fact that mitoKATP exist throughout eukaryotes.

MitoKATP is involved in the regulation of mitochondrial ionic homeostasis (see above). Importantly, a cytoprotective effect of mitoKATP activation has been observed, possibly due to the modulation of the rate of ROS generation in mitochondria. In accordance, mitoKATP has been proposed to play a role in ischemic preconditioning (IP) consisting of brief sublethal ischemic periods that are capable of protecting against subsequent massive ischemia. Similarly, in plant mitochondria, mitoKATP channel is proposed to be involved in the prevention of ROS formation.

Calcium-Dependent Potassium Channels

Two types of calcium-activated potassium channels have been described in various systems: mitoBKCa (big conductance potassium channel) and mitoIKCa (intermediate conductance channel). MitoBKCa (KCa1.1), displaying a conductance of 100–300 pS, has been observed by direct patch clamping of mitoplasts of mammalian cells as well as in planar lipid bilayer experiments. The channel has been identified in glioma cell

lines as well as in ventricular cells, rat skeletal muscle, and brain. Evidence for its presence in mitochondria has also been provided by Western blot, electron microscopy, and immunofluorescence microscopy. The channel is activated by μM concentration of calcium, and is blocked by specific inhibitors charybdotoxin, iberiotoxin, and paxilline. Concerning the molecular nature of mitoBKCa, it seems to coincide with the PM-located BKCa and/or its alternatively spliced forms.

MitoBKCa has been proposed to be activated under pathophysiological conditions that increase mitochondrial Ca^{2+} uptake, thus preventing excessive mitochondrial Ca^{2+} accumulation (by partially depolarizing the IMM, the driving force for calcium influx is reduced) and may also play a physiological role to fine-tune mitochondrial volume and/or Ca^{2+} accumulation under conditions of increased cardiac workload. Opening of mitoBKCa, similarly to mitoKATP, has been reported to protect against damage to the heart and other organs caused by ischemia and reperfusion. Interestingly, mitoBKCa activity has been revealed also in potato, tomato, and maize mitochondria by swelling measurements, and a large-conductance Ca^{2+} -activated potassium channel has been described in potato tuber mitochondrial fractions incorporated into an artificial planar lipid membrane. The mitoBKCa channel in plant mitochondria may function as a possible signaling link between matrix calcium levels and the mitochondrial membrane potential.

The mitoIKCa (KCa3.1) has been recently observed by patch-clamping mitoplasts isolated from human colon carcinoma cells. This channel has been detected in other cell types, namely in HeLa of human cervix adenocarcinoma origin and in mouse embryonic fibroblasts. The channel is selectively inhibited by clotrimazole and TRAM-34. The biophysical and pharmacological properties of the mitoIKCa and of the PM IKCa channels of the same cells are indistinguishable. MitoIKCa may have a protective role similar to that proposed for mitoBKCa and mitoKATP channels; however, so far its physiological role has not been studied in detail.

MitoKv1.3

Kv1.3 is a highly selective channel expressed in the plasma membrane of various cells. Its presence in the mitochondria has been reported in T lymphocytes, macrophages, astrocytes, and hippocampal neurons by several groups, using patch clamp and immunochemistry. The molecular identification of the channel activity was obtained thanks to specific inhibitors margatoxin and ShK, and to a genetic model consisting in Kv1.3-less CTLL-2 cytotoxic lymphocytes and CTLL-2 cells stably expressing Kv1.3. Importantly, a hyperpolarization of the mitochondrial membrane potential could be recorded upon inhibition of mitoKv1.3 with specific drugs, indicating that in energized mitochondria the channel is normally active.

The above model pointed out a role of mitoKv1.3 in apoptosis. MitoKv1.3 was identified as a novel target of the proapoptotic Bcl-2 family protein, Bax, and a physical interaction between the two proteins was shown to occur in apoptotic cells. Incubating Kv1.3-positive isolated mitochondria with Bax or Kv1.3-inhibiting Margatoxin and ShK triggered apoptotic events

including membrane potential changes, ROS production, and cytochrome c release, whereas Kv1.3-deficient mitochondria were resistant. After insertion of activated Bax in the outer mitochondrial membrane, the highly conserved Bax lysine 128 is located in the intermembrane space and mimics a crucial lysine in Kv1.3-blocking toxins. Mutation of Bax at K128 (BaxK128E) abrogated its effects on Kv1.3 and mitochondria also in intact cells, indicating a toxin-like action of Bax on Kv1.3 to trigger at least some of the mitochondrial changes typical for apoptosis. The crucial role of Kv1.3 in cell death was demonstrated by the fact that its knockdown in human peripheral blood lymphocytes impaired apoptosis induction by various stimuli.

Two-Pore Potassium Channel TASK-3

Recently TASK-3, a two-pore potassium channel known to reside in the plasma membrane, was identified in mitochondria of melanoma and keratinocyte cells by immunochemical and molecular biology methods. The functional properties as well as the physiological function of the TASK-3 channel in the inner mitochondrial membrane remain to be investigated.

Open Questions

In summary, the mitochondrial potassium channels listed above have a tissue-dependent expression, and the ones for which molecular candidates exist appear to represent subpopulations of channels present also in the plasma membrane. This raises questions concerning the mechanism of differential targeting of the channels and also casts some doubts on the effective presence of these channels in mitochondria, even though an analogous multiple localization has been established for various other proteins (e.g., kinases). The several mitochondrial proteomic studies published so far have failed to recognize mitochondrial channels except mitochondrial porin. This presumably reflects technical difficulties ascribable to the hydrophobic nature and especially to the low abundance of channel proteins. Genetic approaches may be useful to obtain conclusive evidence on the molecular identity and localization of some of the IMM channels. Using a biochemical approach, the observation that the abundance of a protein in various membranous fractions increases along with that of mitochondrial markers, while markers of contaminating membranes (PM and endoplasmatic reticulum) decrease, may be considered good evidence for a mitochondrial location. Last but not least, observation of a channel by patch clamp in swollen mitoplasts, that is, in the inner membrane, directly proves its presence in that membrane. A comparative proteomic/genetic approach combined with a systematic RNA interference screening may give the link between the genes coding for potassium channels and the mitochondrial potassium channels.

Glossary

Double-stranded RNA RNA structure that is formed either inter- or intra-molecularly between two complementary sequences. The base pairs that are normally found in RNA include A-U, G-C, and G-U. A stable RNA double strand may exist even when the complementarity is short or not continuous.

Polycistronic RNA transcript RNA that contains more than one functional RNA species. Polycistronic RNAs are common in bacteria, including primary transcripts of operons encoding rRNA–tRNA, tRNA, tRNA–mRNA, and mRNA. Polycistronic RNAs consist of a leader sequence preceding the first gene, a trailer sequence following the last gene, and spacer sequences in between the genes.

Ribonuclease (RNase) Enzyme that degrades a RNA molecule by cutting phosphodiester bonds. An endoribonuclease cleaves RNA at internal locations. An exoribonuclease removes one nucleotide at a time in either 3'→5' or 5'→3' direction.

RNA polarity RNA backbone is made of ribose sugars linked together by phosphodiester bonds at the 5' and 3' carbon atoms of ribose rings, conferring RNA directionality, or polarity. A cellular RNA usually contains one or three free phosphate groups at the 5'-end, and a free hydroxyl group at the 3'-end.

Sedimentation coefficient (S) The S value, determined by the mobility of a particle in a centrifugal field, is a measure of the size of the macromolecule or a complex of multiple macromolecules. The higher the S value the larger the molecule.

Transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs) constitute the large majority of cellular RNA in bacteria. In exponentially growing *Escherichia coli* cells, rRNAs and tRNAs account for nearly 80% and 15% in total RNA, respectively. The rRNAs and numerous ribosomal proteins form large complexes known as ribosomes, which are the machinery for protein synthesis. tRNAs work in protein synthesis as carriers of specific amino acids that are added to defined peptide sequences by the ribosome. Both tRNAs and rRNAs are very stable, being functional in generations of cells once they are made. Growing bacterial cells constantly synthesize large amount of tRNAs and rRNAs to keep up with the need for protein synthesis.

A universal feature for all tRNAs and rRNAs is that they are transcribed as precursors that require extensive processing to form the mature, functional forms. In bacteria, the primary transcripts contain extra sequences at both 5'- and 3'-termini of the mature RNA sequences. The extra sequences are removed precisely by specific ribonucleases. This article describes nucleolytic processing pathways that are best understood in model bacteria such as *E. coli* and *Bacillus subtilis*. In addition, numerous nucleotides are modified post-transcriptionally in both tRNAs and rRNAs, which is not discussed in this article.

Processing of Pre-tRNAs

Mature bacterial tRNAs are relatively short molecules ranging from 73 to 95 nucleotides in length. The tRNAs fold into cloverleaf structures at the two-dimensional level (Figure 1), and adopt inverted L structures at the three-dimensional level. Such structures are likely formed prior or during processing. The numbers of tRNA species range from 36 to over 100 in bacteria. In most cases, multiple tRNAs can be charged by one

of the 21 amino acids. The 3'-end of mature tRNAs contain the invariable trinucleotide cytidylate–cytidylate–adenylate (CCA). Specific amino acids can be covalently attached to the 3'-terminal A residue. In bacteria, the CCA is generally encoded by the tRNA gene. However, many bacteria contain CCA-less tRNA genes, and CCA is added post-transcriptionally to these tRNAs.

Our knowledge of tRNA maturation is most advanced in *E. coli*, an organism in which most, if not all, ribonuclease activities have been identified and studied in detail. Bacterial ribonucleases can be divided into endoribonucleases and exoribonucleases. Endoribonucleases responsible for intracellular RNA processing and degradation generally cleave RNA at specific sites, generating 5'-phosphate and 3'-hydroxyl end groups in the resulting fragments. All of the eight known exoribonucleases in *E. coli* digest RNA from the 3' to 5' direction, generating nucleoside-5'-monophosphates. However, exoribonucleases digesting RNA from 5' to 3' exist in bacteria, such as RNase J1 in *B. subtilis*.

Structure of Primary tRNA Transcripts

The large numbers of tRNA genes in each bacterium are organized into various transcriptional units that are located throughout the genome. For instance, tRNA genes in *E. coli* may exist as monocistronic genes, as operons containing a group of tRNA genes transcribed together, and as part of the operons that also contain genes encoding rRNAs or mRNAs. In *Mycoplasma genitalium*, a model bacterium for minimum genome, 27 of the 36 tRNA genes are arranged into five polycistronic tRNA operons, and the rest are probably monocistronic.

As illustrated in Figure 1, the primary tRNA transcripts may contain extra sequences at both 5'- and 3'-termini of each

Figure 1 tRNA processing pathways in various bacteria. The primary transcripts contain extra sequences (marked in dark green lines) at both ends of the mature tRNAs (colored in orange). These extra sequences are removed by various endo- or exo-ribonucleases that are indicated in blue color. The suggested order of RNase actions is indicated by numbers in the parenthesis. Processing of most pre-tRNAs in *E. coli* (a) is initiated by RNase E cleavage in the 3'-trailer sequence. If the 3'-extra sequence is long (right part), it can be shortened exonucleolytically by RNase II or PNPase. Final maturation of the 3'-end requires exonucleolytic trimming, mainly by RNase T and PH and less efficiently by RNase D, II, and BN. If the 5'-extra sequence blocks 3'-maturation such as by forming base pairs, RNase P may cleave first, followed by exonucleolytic trimming of the unblocked 3'-end. Otherwise, both ends can be matured simultaneously. In *B. subtilis* (b), CCA-less pre-tRNAs are cleaved by RNase P to generate the mature 5'-end and by RNase Z downstream of the discriminator (left part). CCA is then added by tRNA nucleotidyl transferase. CCA-containing pre-tRNAs (right part) undergo exonucleolytic maturation at the 3'-end by RNase PH, and possibly also RNase R and YhaM. A long 3'-trailer may be shortened prior to maturation by the exoribonucleases. In *T. maritima* (c), RNase P and Z cleavages generate mature termini from CCA-containing pre-tRNAs. (d) Exonucleolytic trimming by RNase R can generate mature 3'-end for *M. genitalium* tRNA. Maturation of the 3'-end does not require prior removal of the 5'-extra sequence by RNase P. Modified from Li Z, Gong X, Joshi VH, and Li M (2005) Co-evolution of tRNA 3' trailer sequences with 3' processing enzymes in bacteria. *RNA* 11: 567–577, with permission from Cold Spring Harbor Laboratory Press.

tRNA. A monocistronic tRNA transcript contains a leader sequence from transcription start site to the residue upstream of the 5'-end of mature tRNA, and a trailer sequence from the residue immediately downstream of the 3'-terminus of tRNA to the end of the transcript. The transcription terminator sequences are usually copied into the 3'-trailers of tRNA transcripts. Polycistronic transcripts contain an additional spacer sequence between each of the mature RNA. The leader, spacer, and trailer sequences are removed by ribonucleases in sequential orders during tRNA processing.

Processing at the 5'-End of Bacterial tRNA Precursors

The 5'-leaders of tRNAs are removed by an endoribonuclease RNase P, an ubiquitous essential enzyme. In most cases, RNase P is a complex formed by an RNA and a protein. The RNA subunit catalyzes the cleavage of the 5'-leader sequence precisely upstream of the mature 5'-end. RNase P is found in all organisms except in *Aquifex aeolicus* where RNase P has not been identified but similar activity exists.

RNase P recognizes tRNA precursor by interacting with the pre-tRNA at multiple sequence and structural domains. Some key interactions include the formation of base pairing of RNase P RNA with the discriminator and CCA sequence of tRNA. These interactions place the 5'-end of tRNA at the catalytic center of the RNase P RNA. The endonucleolytic cleavage by RNase P releases the leader and generates 5'-phosphate and 3'-hydroxyl end groups in the products. In *E. coli*, RNase P cleaves 5'-leader less efficiently if a long 3'-trailer is also present in the pre-tRNA.

Processing of tRNA 3'-End in *E. coli*

Processing at the 3'-end is more complicated because bacteria have developed different pathways to handle this problem. In *E. coli*, multiple enzymes are involved in removing the 3'-trailers (Figure 1(a)).

The 86 tRNAs identified in *E. coli* contain encoded 3'-terminal CCA in all of them. In most cases, the endoribonuclease RNase E carries out the first step of tRNA maturation by cleaving in the 3'-trailers or spacer sequences in the primary tRNA transcripts, separating individual pre-tRNAs. RNase E recognizes and cleaves at A-U-rich positions that are usually a few nucleotides downstream of the 3'-end of tRNAs (Figure 1(a), left). The intermediates with short 3'-trailers are then cleaved efficiently by RNase P to generate the mature 5'-end. The few 3'-extra residues are removed by exoribonucleases, mainly RNase T and PH. Other exoribonucleases, including the tRNA-specific RNases D and BN (also known as RNase Z and can act as an endoribonuclease), and the nonspecific RNase II, remove the 3'-extra residues less efficiently. These enzymes may contribute to normal tRNA 3'-maturation and become essential in this process in the absence of RNase T and PH. In a few cases, RNase E cleaves further downstream (Figure 1(a), right). The resulting longer 3'-trailer sequences are shortened by the nonspecific exoribonucleases, RNase II and polynucleotide phosphorylase (PNPase), prior to the actions of RNase P, T, and PH.

An interesting point of the exonucleolytic 3'-maturation is that all the processing exoribonucleases are sensitive to the double-stranded structure of the amino acid stem. The structure may serve to stop the exonucleolytic trimming reaction at the end of CCA. In most cases, the stem in pre-tRNAs ends at the base pair between the first residue at the mature 5'-end and the residue upstream of the discriminator. For such precursors, the exonucleolytic trimming reactions may occur simultaneously with RNase P action. Some tRNA precursors contain extended double strand in which the discriminator and CCA sequence may form base pairs with part of the 5'-leader. In such cases, the 5'-leader must be removed first to

unblock the 3'-region before final exonucleolytic maturation of the 3'-end.

Maturation of tRNA 3'-End in Other Bacteria

The maturation pathway found in *E. coli* may also be employed by a number of other bacteria, mainly in the proteobacteria β - and γ -subdivisions, and occasionally in the α -subdivision. These bacteria contain RNase E as well as three tRNA-specific exoribonucleases RNase T, PH, and D, with a few exceptions in which at least one of the three enzymes exists.

The CCA-containing and CCA-less tRNAs in *B. subtilis* appear to be matured by different mechanisms at the 3'-end (Figure 1(b)). The 3'-end of the CCA-less pre-tRNAs is matured in two steps. First, the endoribonuclease RNase Z cleaves the pre-tRNA after the discriminator residue, similar to the way its eukaryotic counterparts work. The CCA sequence is then added by tRNA nucleotidyl transferase. It is interesting that RNase Z is sensitive to the first C residue in CCA sequence, making it unlikely to cleave CCA-containing pre-tRNAs. In addition, RNase Z cleavage at the 3'-end may occur before the removal of 5'-leader, although it can be less efficient in the presence of a long 5'-leader. The 3'-trailer sequences in CCA-containing pre-tRNAs are probably shortened first by activities not yet identified. The shorter 3'-tails are then removed exonucleolytically. RNase PH seems to be the most important RNase in this final step. Other exoribonucleases, such as RNase R, PNPase, and YhaM, may also contribute to 3'-exonucleolytic maturation of CCA-containing tRNAs.

The bacterium *Thermotoga maritima* presents a simpler tRNA processing pathway. The RNase Z in *T. maritima* cleaves at a position immediately after the encoded CCA, generating mature 3'-end directly (Figure 1(c)).

RNase Z is present throughout bacterial, archaeal, and eukaryotic kingdoms. The eukaryotic counterparts of this RNase seem to cleave pre-tRNAs immediately after the discriminator residue. It is not clear why RNase Z enzymes in different bacteria work differently in tRNA 3'-processing. As mentioned above, RNase Z in *B. subtilis* efficiently cleaves CCA-less pre-tRNAs but is inhibited by CCA sequence. RNase Z in *T. maritima* appears to have evolved to cleave directly at the mature 3'-end of CCA-containing pre-tRNAs. RNase Z in *E. coli* was initially identified as an exoribonuclease RNase BN. It is now known to work as both endo- and exoribonuclease. *E. coli* RNase Z is also sensitive to CCA sequence, and it works poorly for 3'-maturation of *E. coli* tRNAs. Consistent with its role in tRNA maturation, RNase Z is essential for *B. subtilis* viability but is dispensable for *E. coli* growth.

Mycoplasma species must have developed a unique pathway for tRNA 3'-processing as none of the 3'-processing enzymes described above exists in this group of bacteria. The only exoribonuclease that seems to be present in mycoplasmas is an RNase belonging to the RNase II/R family. The RNase R ortholog in *M. genitalium* has some catalytic features similar to those of *E. coli* RNase R, such as the ability to efficiently degrade structured RNA. Remarkably, purified RNase R from *M. genitalium* can generate mature 3'-end from a pre-tRNA *in vitro*, making it a candidate for the maturation of tRNA 3'-end. In contrast, RNase R from *E. coli* degrades such

pre-tRNA completely. It is likely that mycoplasmas have adopted a novel mechanism to remove the 3'-trailers of pre-tRNAs by a single exoribonuclease in one step (Figure 1(d)).

Processing of Pre-rRNAs

Bacteria contain 5S, 16S, and 23S rRNAs, where S is the sedimentation coefficient used as a measure of RNA size. The 5S, 16S, and 23S rRNAs in *E. coli* are 120, 1542, and 2904/2905 nucleotide in length, respectively. The length of the rRNAs may vary slightly in other bacteria. The rRNAs fold into complicated secondary and tertiary structures, most likely during or prior to their maturation. One of each rRNA species and numerous ribosomal proteins are assembled into a ribosome, with 5S and 23S in the large (50S) ribosome subunit and 16S in the small (30S) ribosome subunit. The rRNAs not only provide the structural core of the ribosome, but may also be catalytically active in protein synthesis reactions. For instance, the RNA component of the 50S subunit may catalyze peptide bond formation. Pre-rRNA processing shares some of the RNases that are involved in tRNA maturation.

Structure of Primary rRNA Transcripts

The three rRNAs are usually encoded in the same operon and are co-transcribed together. In most bacterial genomes, the rRNA operons are duplicated to ensure the production of sufficient rRNA transcripts. In *E. coli*, there are seven rRNA operons (*rrn*), each containing rRNA genes in the order of 16S, 23S, and 5S. There are one or two tRNA genes between 16S and 23S rRNAs. At the distal region, there are two more tRNA genes downstream of 5S rRNA in the *rrnC* and *rrnH* operons, and one tRNA gene and one additional 5S rRNA gene in the *rrnD* operon. In *B. subtilis*, 16S, 23S, and 5S rRNAs are co-transcribed from 10 *rrn* operons. Majority of the primary transcripts also contain tRNAs that are located upstream of 16S rRNA, in between 16S and 23S, or downstream of 5S. In *M. genitalium*, the 16S, 23S, and 5S rRNAs are encoded by a single operon with short spacer regions in between the rRNAs.

As shown in Figure 2, the primary rRNA transcripts in *E. coli* and *B. subtilis* may contain extra sequences flanking each of the functional RNA species. These include the sequence upstream of the 16S rRNA, the spacer region between each of the rRNA or tRNA species, and the sequence downstream of the most distal RNA ended by a terminator. The rRNAs may be folded right after they emerge during transcription, and are associated with ribosomal proteins. It can be expected that many of the nucleolytic processing and ribosome assembly events may interfere with each other and can be co-transcriptional. Importantly, the precursor sequences form extended double-stranded regions at the termini of each rRNA species. As described below, these double-stranded regions are important structural determinants for various processing events.

Primary Processing Reactions

In *E. coli* and *B. subtilis*, the 30S primary rRNA transcripts are first processed by RNase III, an endoribonuclease that

Figure 2 rRNA maturation pathways in *E. coli* (upper part) and *B. subtilis* (lower part). The rRNA sequences (colored in orange) are separated by extra sequences (marked in green lines) in the 30S primary transcripts. The RNases involved in rRNA maturation at indicated positions are colored in blue. Note the similar organization of rRNA transcripts and primary processing step in both bacteria. *E. coli* and *B. subtilis* differ in secondary processing by employing different sets of RNases. Modified from Li Z and Deutscher MP (2004) Exoribonucleases and endoribonucleases. In: Curtiss R, III (ed.) *EcoSal—Escherichia coli and Salmonella: Cellular and Molecular Biology*, ch. 4.6.3. Washington, DC: ASM Press.

recognizes and cleaves double-stranded RNAs (Figure 2). RNase III cleaves both RNA strands in the stem flanking 16S and 23S rRNAs, separating the three rRNA species into fragments which undergo further processing to form mature RNAs. This process is so efficient in exponentially growing cells that essentially no 30S RNA is detectable at steady state. Other bacteria may also employ RNase III cleavage as the primary step of processing because RNase III is widely distributed in bacteria and rRNAs are organized in similar transcripts. The subsequent processing events are relatively well studied in *E. coli* and *B. subtilis*.

Generation of Mature rRNAs in *E. coli*

16S rRNA

RNase III cleavages in the stem flanking 16S rRNA generate a precursor of 17S in size, containing 115 extra residues at the 5'-end and 33 at the 3'-end (Figure 2, upper part). Maturation of the 5'-terminus is dependent on the sequential actions of two homologous endoribonucleases, RNase E and RNase G. First, RNase E cleavage at 66 residues upstream of 16S removes 49 nucleotides, generating a 16.3S product. Subsequently, RNase G removes the remaining 66 nucleotides rapidly, generating the mature 5'-end. When RNase E is inactive, RNase G is able to remove the entire 115 residues at a much reduced rate. In the absence of RNase G, the 16.3S product is slowly

converted to a product containing four to five extra residues at the 5'-end by RNase E. No other activity can process the 115 leader sequence when both RNase E and RNase G are missing. Maturation of 5'-end likely occurs in partially or completely assembled ribosomes as purified ribosomes containing the 5' extra residues can be cleaved by RNase E and G at the correct sites.

Maturation of the 3'-end of 16S rRNA is thought to be endonucleolytic, even though the activity responsible for this event has not yet been identified. In supporting this idea, inactivation of the exoribonucleases responsible for 3'-maturation of other RNAs has no effect on the 33 extra residues. In addition, the 33 residues appear to be removed in one step, forming no intermediate between the 3'-mature terminus and the +33 precursor. It is also known that 3'-processing is slightly inhibited by the blockage of 5'-maturation.

23S rRNA

The RNase III cleavage produces processing intermediates of 23S rRNA containing seven to nine extra residues at the 3'-end and either three or seven extra residues at the 5'-end (Figure 2, upper part). Maturation of the 3'-end requires the exoribonuclease RNase T. In the absence of RNase T, little mature 3'-end is made, and products ranging from one to six extra residues accumulate. These products must be converted from RNase III cleavage products by other exoribonucleases. In cells deficient

in RNase PH, D, II, and BN in combination, but retaining RNase T, the majority of 23S rRNA is matured at the 3'-end, indicating that RNase T plays a major role in generating the mature 3'-end. In such cells, slightly more pre-23S rRNA containing seven to nine extra residues at the 3'-end was detected, suggesting that the missing exoribonucleases may be responsible for shortening these products before RNase T action. Interestingly, RNase T removes the last extra residues much more efficiently from pre-23S rRNA in the ribosome than from isolated pre-23S rRNA, suggesting that 3'-maturation occurs during or after ribosome assembly.

Removal of the three or seven extra residues at the 5'-end occurs independently of 3'-maturation. Limited evidence suggests that 5'-maturation is probably carried out by an endoribonuclease other than RNases III, E, or G. It is also known that generation of mature 5'-terminus requires protein synthesis conditions.

5S rRNA

RNase III cleavage around 23S rRNA releases a downstream product containing 5S rRNA (Figure 2, upper part). For most rRNA transcripts, this processing intermediate is 9S in size. The 9S RNA is rapidly cleaved by RNase E at sites flanking 5S sequence, generating a pre-5S RNA molecule that contains three extra residues at each end. The 5'-extra residues are thought to be removed by an exonucleolytic activity. However, this 5'- to 3'-exoribonuclease has never been identified, and it is also likely that an endoribonuclease makes sequential cleavages to generate the mature 5'-terminus. Removal of the 5'-extra residues is independent of 3'-maturation of 5S RNA.

Maturation of the 3'-end is dependent on the exoribonuclease RNase T. RNase T can remove all three extra residues. Cells having RNase T contain essentially only mature 5S rRNA, regardless of whether other exoribonucleases are present or not. In the absence of RNase T, other exoribonucleases can only remove the residue at the +3 position, leaving a product with two extra residues at the 3'-terminus. Similar to 23S rRNA, 5S rRNA is matured at the 3'-end by RNase T much more efficiently in the ribosome than in isolated form.

RNase T is one of the key exoribonucleases for 3'-maturation of tRNA and other small, stable RNAs. This enzyme is absolutely required for 3'-processing of 5S and 23S rRNAs, and is the only RNase responsible for tRNA end turnover. A common feature present in all of these RNAs is the stable stem structures formed between the 5'- and 3'-terminal sequences (Figure 3). As mentioned above, the 3'- to 5'-exoribonucleases are sensitive to double strands in the RNA and they tend to stop trimming when the 3'-end becomes close to the terminal stem. Most of the RNAs undergoing exonucleolytic 3'-maturation contain four single-stranded residues at the mature 3'-end located downstream of the stem. Thus, the terminal stem structure may serve as a 'molecular ruler' for exonucleolytic digestion to stop at the correct downstream position. RNase T seems to be able to go closer to the double-stranded region than other exoribonucleases (Figure 3). This ability explains why it is the only enzyme that can generate mature 3'-end for 5S and 23S rRNAs that contain a one- and two-residue overhang, respectively. For similar reasons, RNase T is the only enzyme that can trim the uncharged CCA sequence of tRNA species for certain amino acids. Such tRNAs containing shortened CCA sequence are nonfunctional and can be repaired by tRNA nucleotidyl transferase.

Generation of Mature rRNAs in *B. subtilis*

16S rRNA

The pre-16S rRNA generated by RNase III cleavage contains 67 extra residues at the 3'-end and 76 or 140 extra residues at the 5'-end from rRNA transcripts encoded by different *rnm* operons. Removal of the extra residues follows similar steps as described in *E. coli*; however, different ribonucleases may be used in *B. subtilis*. In fact, RNase E and G, the enzymes responsible for 5'-maturation of 16S RNA in *E. coli*, are not present in *B. subtilis*. Instead, *B. subtilis* employs an as-yet unidentified enzyme(s) to cleave the 76 extra residues at +38 or 140 extra residues at +102. These shorter products are then removed by an essential enzyme RNase J1 to generate the mature 5'-terminus (Figure 2, lower part). Interestingly, RNase J1 is a large protein exhibiting both endoribonuclease and 5'- to

Figure 3 3'-Exonucleolytic trimming is hindered by RNA double-stranded structures in *E. coli* RNAs. The 3'-extra residues (marked in dark-green) in pre-tRNA, pre-23S, and pre-5S rRNA sequences (colored in orange) are removed by exoribonucleases during the final maturation step. The exoribonucleases are generally sensitive to RNA structures, and their trimming stops when the 3'-end is close to the stem formed between the termini of the RNAs. In all cases, RNase T (colored in blue) can trim residues closer to the stem than other exoribonucleases. This property of RNase T is consistent with its role as a major 3'-maturation enzyme for tRNAs, and as the sole RNase for the 3'-maturation of 23S and 5S rRNAs as well as for tRNA end turnover. Modified from Li Z and Deutscher MP (2004) Exoribonucleases and endoribonucleases. In: Curtiss R, III (ed.) *EcoSal—Escherichia coli and Salmonella: Cellular and Molecular Biology*, ch. 4.6.3. Washington, DC: ASM Press.

3'-exoribonuclease activities. Maturation of the 5'-end of 16S rRNA is probably carried out by the exonucleolytic activity of this enzyme. The RNase(s) responsible for 3'-maturation is yet unidentified.

23S rRNA

RNase III cleavage produces a pre-23S rRNA containing 64 extra residues at 5'-end and 32 extra residues at 3'-end. These extra residues present in a long double-stranded region are removed by another double-strand-specific endoribonuclease Mini-III, which cleaves both sides of the stem to generate mature termini in one step (Figure 2, lower part). However, Mini-III is not essential for 23S rRNA maturation. It has been recently reported that in *B. subtilis* cells lacking Mini-III, RNase J1 and the 3'- to 5'-exoribonucleases RNase PH and YhaM generate mature 5'- and 3'-termini, respectively. RNase J1 removes the 5'-extra residues in a way consistent with its exonucleolytic activity.

5S rRNA

Pre-5S rRNA is released from the primary rRNA transcripts by RNase III cleavage. This processing intermediate extends from RNase III cleavage site at the 3'-side of 23S rRNA to the 3'-terminus of the entire transcript. 5S rRNA is matured endonucleolytically by RNase M5 (Figure 2, lower part). RNase M5 is essential for maturation of 5S rRNA but is dispensable for cell viability.

Generation of Mature rRNAs in Other Bacteria

Unlike the ubiquitous primary processing by RNase III, the secondary processing pathways vary among bacteria. For instance, RNase E-dependent maturation of 16S and 5S rRNAs may only occur in relatively small number of bacteria as this enzyme seems to be limited in proteobacteria. RNase G, and in some cases enzymes such as both RNase E and G, is present in a broader range of bacteria including proteobacteria, actinobacteria, chlamydiae, clostridia, quifecales, thermotogales, and the *Chlorobium*–*Flavobacterium* group. However, it remains to be determined if the 5'-end of 16S rRNA is matured by RNase G or the E/G-like enzyme in these bacteria, especially when RNase E is not present.

RNase J1 is widely distributed throughout the bacterial and archaeal kingdoms, and is a good candidate for 5'-maturation of 16S rRNA in such organisms. *Sinorhizobium meliloti* harbors genes encoding both RNase E and J1. Interestingly, it was recently shown that RNase J, but not RNase E, is responsible for the 5'-end maturation of 16S rRNA in *S. meliloti*.

Mini-III generates mature ends for 23S rRNA, and RNase M5 does the same to 5S rRNA. Mini-III is confined in Firmicutes and the Cyanobacteria. In bacteria lacking Mini-III, 23S rRNA can be matured by exonucleolytic activities, such as RNase J1 for the 5'-end and RNase T, PH, and YhaM for the 3'-end. RNase M5 is confined in low G + C Gram-positive bacteria.

It was recently suggested that the exoribonuclease RNase R may be responsible for the maturation of 3'-termini of 16S and 5S rRNAs in *Pseudomonas syringae*. In the absence of RNase R, 16S and 5S rRNA products that contain extra residues at the 3'-ends accumulate at low temperature (4 °C).

The Consequences of Defective Processing

tRNAs

Defects in pre-tRNA processing would generate tRNA molecules that are processed incompletely or incorrectly. Such tRNAs are most likely nonfunctional because of the strict requirements for correct tRNA structure in protein synthesis. For instance, aminoacylation absolutely depends on the CCA sequence at the 3'-end of mature tRNA. Cells die if the major activities of tRNA processing fail, such as when either RNase P or RNase E is inactivated. However, a number of mechanisms may prevent more trivial defects in tRNA processing from becoming lethal. In most cases, there is more than one specific tRNA for each amino acid. If one specific tRNA is not processed correctly, others may still be functional. The 3'-maturation mechanism that involves multiple redundant exoribonucleases can avoid incomplete processing due to the failure of one RNase. Consistent with this notion, none of the tRNA maturation exoribonucleases RNase T, PH, D, II, or BN is essential in *E. coli*. Deficiency in one or a combination of up to four of these RNases slows down cell growth to levels depending on the importance of the missing enzymes in 3'-maturation, whereas inactivation of all five leads to cell death. If the CCA sequence is accidentally shortened or removed, tRNA nucleotidyl transferase can repair it to restore tRNA function.

rRNAs

Defective processing of pre-rRNA appears to be better tolerated than that of pre-tRNA because incompletely processed rRNAs are sometimes found in ribosomes that are active in protein synthesis. When the primary processing fails, cells may use alternative processing activities. In *E. coli* lacking RNase III, the primary transcripts can be cleaved by RNase E, G, and P. However, these cleavages are not as efficient as those carried out by RNase III, leading to the accumulation of primary rRNA transcripts in RNase III mutants. The cleavage products generated by the alternative enzymes can also be difficult to process in secondary processing reactions. In fact, 23S rRNA is not completely matured in RNase III mutants. Another example is that the 3'-termini of 23S and 5S rRNAs are not matured in RNase T-deficient cells. The immature rRNAs must be functional because mutants lacking RNase III or RNase T are viable.

Unlike in *E. coli*, RNase III is essential in *B. subtilis*. However, RNase III mutation leads to the accumulation of lower levels of primary rRNA transcripts in *B. subtilis* than in *E. coli*, probably due to the availability of more effective alternative processing activities in *B. subtilis*. In the absence of RNase III, RNase J1, Mini-III, and M5 can still generate mature rRNAs.

Quality Control

Accumulation of incompletely or incorrectly processed RNAs may be deleterious to cells. Such RNAs may be removed by RNA quality-control mechanisms. For instance, a mutant tRNA^{Trp} in *E. coli* is processed inefficiently and the majority is degraded at the precursor level. PNPase, a processive phosphorolytic exoribonuclease, and poly(A) polymerase play important roles in the degradation of this mutant tRNA. In the absence of both enzymes, a product containing the tRNA

and the entire 31-residue 3'-trailer accumulates to high level. Poly(A) polymerase probably facilitates degradation by adding a poly(A) tail to the stem present at the end of the 3'-trailer. The poly(A) tail may help to recruit exoribonucleases that are sensitive to stem structures.

Glossary

Cholestasis A liver disorder in which bile flow is impeded. Clinical signs of cholestasis are a disproportionate increase in the serum alkaline phosphatase or gamma glutamyl transpeptidase compared to the serum alanine aminotransferase (ALT) or aspartate aminotransferase (AST). The symptom most characteristic of cholestasis is pruritus.

Hepatic encephalopathy A disturbance in consciousness that occurs in patients with advanced liver disease. Manifestations can range from subtle changes in personality to frank coma.

Micellar Pertaining to a colloid particle formed by the aggregation of small molecules. Micelles in bile contain bile acids, phospholipids, and cholesterol.

Mitochondria Organelles important in energy metabolism that are found in nucleated cells throughout the body.

Ursodeoxycholic acid A naturally occurring bile acid, the major constituent of bear bile, comprises approximately 1–2% of human bile and is used to treat primary biliary cirrhosis.

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease that is characterized by the continuing destruction of interlobular bile ducts, progressive fibrosis, and, if not treated, the eventual development of cirrhosis and liver failure. In contrast to patients seen more than two decades ago, most of whom had symptoms of fatigue, pruritus (itching), or jaundice, the majority of PBC patients who are diagnosed now are asymptomatic. The prognosis of PBC has improved greatly during the past decade. This is due to the two factors: its detection at earlier stages and the efficacy of treatment with ursodeoxycholic acid (ursodiol, UDCA), particularly in patients who have early-stage disease. Patients with early-stage PBC treated with ursodiol have a normal life expectancy for up to 20 years after diagnosis. Survival of patients with histologically more advanced PBC, stages III and IV, is not improved with ursodiol. There is general agreement that all patients with PBC should be treated with ursodiol, but there is no consensus about the treatment of patients who do not respond fully to ursodiol. The author has found that the addition of colchicine and methotrexate to ursodiol in those patients who failed to respond fully to ursodiol improved symptoms, biochemical tests of liver function, and liver histology in 80% of nonresponders.

Epidemiology

PBC was once considered a rare disease. However, increased awareness of PBC has led to earlier and more frequent diagnoses. In some series, it accounted for almost 2% of deaths due to cirrhosis. In a study from England, there was an annual incidence of 5.8 cases per million population and a point prevalence of 54 cases per million. The prevalence in the US is at least that high. Estimates place the number between 50 000 and 100 000 patients. The etiology is unknown but is most likely related to altered immunoregulation. The high but not total concordance of PBC in identical twins suggests that some triggering event is required to initiate PBC in a genetically

susceptible individual. The prevalence of PBC in families with one affected member is estimated to be 1000 times greater than that in the general population. A close association of PBC with genetic variants at the human leukocyte antigen (HLA) class II interleukin (IL)12A and IL12RB2 loci has recently been reported. A number of environmental causes have been implicated in the pathogenesis of PBC, including bacteria, viruses, smoking, and exposure to halogenated hydrocarbons such as those found in some cosmetics. Molecular mimicry has been the most widely proposed mechanism for the initiation of PBC. The most robust data supporting a role for molecular mimicry implicate a unique ubiquitous, xenobiotic-metabolizing gram negative bacterium, *Novosphingobium aromaticivorans*, that is found in soil throughout the world. This bacterium has four lipoyl domains with homology strikingly similar to the human lipoylated autoantigens that have been implicated in the pathogenesis of PBC. These lipoyl domains can be found by polymerase chain reaction (PCR) in approximately 20% of all individuals, in both normals and those with PBC, and are capable of metabolizing environmental estrogens to active estradiol. Almost 100% of patients with antimitochondrial antibody (AMA)-positive PBC have very high antibody titers against the lipoyl domains of *N. aromaticivorans*. Some of the most compelling evidences for an environmental factor as a triggering factor in the etiology of PBC have been derived from epidemiological studies that demonstrated significant geographic clustering of PBC cases in urban areas in northeast England and near waste disposal sites in New York City.

Etiology

Autoantibodies, Antimitochondrial Antibody

PBC is considered to be a model autoimmune disease. Of the patients with PBC, 90–95% are women, a sex distribution similar to that of other autoimmune diseases such as systemic lupus erythematosus. There is an increased incidence of

autoantibodies, including antimitochondrial antibodies, antinuclear antibodies, and antimicrobial antibodies. AMA is detected in 95% of patients with PBC and 98% of patients with a positive AMA have PBC. The major autoantibody found in PBC patients has been called anti-M2. It is principally directed against the dihydrolipoamide acyltransferase component (E2) of the branched keto-acid dehydrogenase and pyruvate dehydrogenase complexes on the inner mitochondrial membrane. Other antimitochondrial antibodies that have been described in PBC, anti-M4, anti-M8, and anti-M9 are most likely artifacts and were not found in a study that employed highly purified human mitochondrial proteins as antigens. The relationship between antimitochondrial antibodies and immunologic bile duct injury is not clear. The mitochondrial antigens are not tissue specific, and their intracellular location should reduce their immunogenicity. Repeated studies have shown that there is no correlation between the presence or titer of AMA and the severity or course of PBC.

Mitochondrial Antigens and the Cellular Immune System

Although there is little evidence that AMA plays a direct role in the pathogenesis of PBC, an interaction between the mitochondrial antigens and the cellular immune system appears to be important. The mitochondrial antigens, normally found in the inner mitochondrial membrane of all cells, are aberrantly expressed in the luminal surface of biliary epithelial cells only in patients with PBC and at an early stage of disease. CD4+ and CD8+ cells are present in high concentration in the portal triads of patients with PBC and often surround and infiltrate necrotic bile ducts. The E2 mitochondrial antigens stimulate interleukin-2 production by peripheral blood mononuclear cells and by T cells cloned from liver biopsies of PBC patients. E2 antigens are recognized by both helper and cytotoxic T cells in PBC. Cytotoxic T cells appear to mediate bile duct epithelial cell necrosis. Autoreactive T lymphocytes isolated from PBC patients are specific for PDC-E2. CD4+ cells that recognize this epitope are 100–150 times more concentrated in liver and regional lymph nodes compared to peripheral blood in patients with PBC while autoreactive CD8+ are 10–15 times more concentrated in liver compared to blood. These cloned CD8+ T cells produce interferon (IFN)- γ in response to PDC-E2. The immunodominant epitope recognized by major histocompatibility complex (MHC) class II-restricted CD4+ T cells in patients with PBC includes amino acids 163–176 of PDC-E2. The immunodominant epitope recognized by MHC class I-restricted CD8+ T cells is similar, amino acids 159–167 of PDC-E2. This region of PDC-E2 also overlaps with the region to which AMAs bind. These data suggest that bile duct epithelial cells expressing this epitope are targeted by CD4+ and CD8+ T lymphocytes in patients with PBC.

Why bile duct epithelial cells express this epitope is still unknown. One possibility is that immunoglobulin IgA that recognizes PDC-E2 is complexed to it as IgA is transcytosed from the basal to apical side of the bile duct epithelial cell en route to its secretion in bile. Serum IgA has been found at mitochondrial surfaces in bile duct epithelial cells and

immune complexes containing PDC-E2, and IgA has been found in bile duct lumens in patients with PBC.

Association with Other Autoimmune Diseases

There is an increased association of PBC with other autoimmune diseases, such as thyroiditis, rheumatoid arthritis, the CREST syndrome (CREST stands for calcinosis, Raynaud's syndrome, esophageal dysmotility, sclerodactyly, telangiectasia), Raynaud's disease, autoimmune chronic hepatitis, and Sjögren's syndrome. Although circulating immune complexes have been demonstrated in some PBC patients, it is unlikely that they play a role in pathogenesis. Only a small percentage of PBC patients have immune complexes. Some PBC patients have an IgM which can fix complement in the absence of demonstrable antigen binding and will give false positive results with many of the assays used to detect immune complexes.

Pathophysiology

The signs and symptoms of PBC are due to the long-standing cholestasis. There is a gradual destruction of small intrahepatic bile ducts that results in a decreased number of functioning bile ducts within the liver. This, in turn, causes retention within the liver of substances that are normally secreted or excreted into bile, such as bile acids, bilirubin, and copper. The increased concentration of some of these substances, for example, bile acids, causes further damage to liver cells. Other substances regurgitate from the liver into blood and soft tissues and cause symptoms such as pruritus. The identity of the substance or substances that cause pruritus is unknown. It is not any of the naturally occurring primary and secondary bile acids. Most data suggest that it is some substance that is secreted into bile and that binds tightly to cholestyramine, a nonabsorbed, quaternary ammonium resin. Possible pruritogens include the naturally occurring opioids and lysophosphatidic acid. Serum levels of endogenous opioids (endorphins and enkephalins) are increased in PBC, and opioid antagonists will relieve itching in some patients. A recent study demonstrated that the activity of autotaxin, the enzyme that converts lysophosphatidylcholine to lysophosphatidic acid, was significantly and uniquely elevated in the sera of patients with cholestasis and pruritus and that lysophosphatidic acid induced scratching when injected into mice and stimulated isolated neurons *in vitro*. The striking hyperlipidemia and xanthoma formations in some PBC patients are also a consequence of long-standing cholestasis. The impaired secretion of bile in patients with clinically advanced PBC causes a diminished concentration of bile acids within the intestinal lumen. The bile acid concentration may fall below the critical micellar concentration and thus be inadequate for complete digestion and absorption of neutral triglycerides in the diet. This causes the striking fat malabsorption seen in some jaundiced PBC patients as well as malabsorption of the fat-soluble vitamins A, D, E, and K. Some PBC patients with Sicca syndrome also have pancreatic insufficiency. The pathogenesis of the osteopenic bone disease that occurs in at least 25% of PBC patients is still unclear. Some data suggest that high concentrations of

serum bilirubin may impede osteoblast function. The clinically important bone disorder is osteoporosis, not osteomalacia, as was once believed.

Pathology

PBC is characterized by portal inflammation, the destruction of interlobular bile ducts, progressive fibrosis, and the eventual development of cirrhosis. PBC is divided into four histologic stages, I–IV. The disease is believed to progress from stage I to stage IV. However, the liver is not affected uniformly in PBC. One biopsy specimen may demonstrate lesions ranging from normal to stage IV. By convention, the histologic stage is the highest stage seen in a biopsy. There are two widely used staging systems, those of Scheuer and Ludwig, both well-known liver pathologists. In the Scheuer classification, stage I is defined by the presence of florid, asymmetric destructive bile duct lesions within portal triads (Figures 1(a) and 1(b)). These lesions are irregularly scattered throughout the portal triads and are often seen only on large surgical biopsies of the liver. The damaged bile ducts are often surrounded by dense collections of lymphocytes, histiocytes, plasma cells, eosinophils, and occasionally true giant cells, a pathologic lesion that is called a granuloma (Figure 1(a)). In the Ludwig classification, stage I is defined by the localization of inflammation to the portal triads. In stage II in the Scheuer classification, there are

reduced numbers of normal bile ducts within some portal triads and increased numbers of poorly formed bile ducts with irregularly shaped lumens in others, a lesion called atypical bile duct hyperplasia (Figure 2). Mononuclear cell inflammation occurs in portal triads and at the beginning of portal fibrosis. In stage II in the Ludwig classification, the inflammation and fibrosis extend beyond portal triads and into the surrounding parenchyma. A diminished number of bile ducts in an otherwise unremarkable appearing needle biopsy of the liver should alert one to the possibility of PBC. In stage III in both classifications, fibrous septa now extend beyond triads and form portal-to-portal bridges (Figure 3). The portal triads are otherwise similar to those in stage II. Stage IV represents the end stage of the lesion, frank cirrhosis, and regenerative nodules. It may be difficult to distinguish this late lesion from other types of cirrhosis. A paucity of normal bile ducts in areas of scarring suggests PBC (Figure 4).

Clinical Findings

The earliest and most common complaint is fatigue. Fatigue, however, is nonspecific and is found in many diseases. The earliest specific complaint in PBC is pruritus, usually worse at bedtime. In some patients, the pruritus begins during the third

Figure 1 (a) Stage I florid bile duct lesion in primary biliary cirrhosis. A damaged bile duct is at the center of a granuloma (Masson trichrome, $\times 124$). (b) Stage I florid bile duct lesion in primary biliary cirrhosis. Epithelial cells have been dislodged from one quadrant of a bile duct (Masson trichrome, $\times 310$).

Figure 2 Stage II primary biliary cirrhosis. Atypical bile duct hyperplasia. Bile ducts are tortuous. None are cut in cross section and there are no visible bile duct lumens (hematoxylin and eosin, $\times 310$).

Figure 3 Stage III primary biliary cirrhosis. Adjacent portal triads are linked by septae that contain mononuclear inflammatory cells and scar tissue (Masson trichrome, $\times 310$).

Figure 4 Stage IV primary biliary cirrhosis. Cirrhotic liver removed at the time of liver transplantation performed because of end-stage primary biliary cirrhosis. Nodule formation is evident and there are no visible bile ducts (Masson trichrome, $\times 54$).

trimester of pregnancy and persists after delivery. Physical examination may reveal hepatomegaly and increased skin pigmentation. The pigment is melanin, not bilirubin, at this early stage. Excoriations, caused by intense itching and an uncontrollable urge to scratch, may be widespread. Jaundice usually presents later in the course of the disease. Kayser–Fleischer rings have been observed in a few PBC patients with longstanding jaundice. Unexplained weight loss may also occur. Rarely, patients with PBC may go undetected until late in the course of the disease when they present with severe jaundice, ascites, or bleeding from esophageal varices. During the course of the disease, some patients with jaundice may develop malabsorption and complain of nocturnal diarrhea, frothy, bulky stools, or weight loss in the face of voracious appetite and increased caloric intake. Fewer than 5% of patients will develop xanthomas (a cutaneous tumor composed of lipid-laden foam cells) but xanthelasma (a planar xanthoma of the eyelids) are more common. Bone pain may occur in PBC patients with osteoporosis, as well as spontaneous collapses of vertebral bodies and hairline fractures of ribs. Fractures of long bones are less common.

Laboratory Tests

Liver function tests reveal a cholestatic pattern. The serum alkaline phosphatase and gamma glutamyl transpeptidase (GGT) are often strikingly elevated. The serum aminotransferases are less elevated and may be normal early in the course of PBC. Serum albumin and prothrombin times are characteristically normal early in the course of the disease while IgM levels are often elevated. The elevated alkaline phosphatase is usually of liver origin. 5'-Nucleotidase and GGT levels parallel the alkaline phosphatase. The serum bilirubin is normal early in the course of the disease but becomes elevated in most patients as the disease progresses. Both direct and indirect fractions are increased. Despite strikingly high serum cholesterol values, occasionally 800–1600 mg dl⁻¹, atherosclerosis is uncommon, most likely because serum high-density lipoprotein (HDL) cholesterol levels are also elevated. AMA is positive in 95% of patients. Serum ceruloplasmin is elevated, in contrast

to Wilson's disease, another disorder with increased retention of copper within the liver. There is an increased incidence of hypothyroidism in PBC that is not always reflected by routine tests of thyroid function. Elevated thyroid-stimulating hormone (TSH) levels will usually identify such individuals.

Diagnosis

The combination of a disproportionately elevated alkaline phosphatase and a positive AMA is sufficient evidence to make a diagnosis of PBC as long as the liver biopsy is consistent with this diagnosis. It is prudent to demonstrate that the bile ducts are patent. Ultrasonography is usually adequate for this purpose. Endoscopic cholangiography (ERCP) is recommended if there is a suspicion of bile duct obstruction on imaging tests or if the AMA is negative in a patient with inflammatory bowel disease. The ERCP is done in this setting to detect primary sclerosing cholangitis. A percutaneous needle biopsy of the liver will confirm the diagnosis, allow histologic staging, and provide a baseline for follow-up biopsies that are done to evaluate the efficacy of medical treatment.

Treatment

Treatment of Symptoms

Pruritus

The nonabsorbed resin, cholestyramine, 4–8 g twice daily with meals, will relieve pruritus in most patients. Commonly prescribed anti-itch medicines such as antihistamines are only helpful early in the course of PBC when itching is not severe. Rifampin, 150 mg twice daily, will control itching in most patients who fail to respond to cholestyramine. Opioid antagonists, such as naloxone and naltrexone, may be effective in the small number of PBC patients who fail to respond to ammonium resins and rifampin.

Fatigue

We noted that modafinil (Provigil), 100 mg in the morning, relieved fatigue in five consecutive PBC patients who had incapacitating fatigue. This observation has now been confirmed in two larger observational studies. In our later study, 43 of 527 PBC patients (7%) had incapacitating fatigue and modafinil relieved fatigue in 70% of the 42 patients who took it. The effectiveness of modafinil appears to be durable in most patients who benefited from it.

Malabsorption

Some patients with PBC and the Sicca syndrome may have concomitant pancreatic insufficiency. This can be treated with pancreatic enzyme preparations given orally. Malabsorption of fat-soluble vitamins is irregular and unpredictable, but deficiencies of vitamins A, D, E, and K may occur in patients who are chronically jaundiced. Patients with low levels of a specific vitamin should be given supplements of it orally.

Anemia and osteoporosis

PBC patients may develop iron-deficiency anemia. This often reflects unrecognized gastrointestinal (GI) blood loss. Upper

endoscopy is indicated to detect esophageal varices or congestive gastropathy. If present, treatment with nonspecific beta blockers such as propranolol or nadolol is effective. Until recently, liver transplantation was the only proven effective treatment for osteoporosis. Now, bisphosphonates such as alendronate and risedronate together with supplemental calcium and vitamin D appear to be equally effective and are recommended in PBC patients who have osteopenia confirmed by bone density studies.

Treatment of the Underlying Disease Process

PBC, if untreated, is a progressive disease that eventually ends in liver failure and the need for liver transplantation. Median survival for symptomatic patients without treatment is approximately 7–10 years. Patients who are asymptomatic at the time of diagnosis have a longer life expectancy than symptomatic patients.

Medical treatment

UDCA, 12–15 mg kg⁻¹ body weight daily, is the only drug approved by the Food and Drug Administration (FDA) for the treatment of the PBC. It decreases serum levels of alkaline phosphatase, alanine aminotransferase (ALT), aspartate aminotransferase (AST), low-density lipoprotein cholesterol and IgM, reduces the risk of developing esophageal varices, and slows histologic worsening. It is safe and well tolerated. Colchicine, 0.6 mg twice daily, and methotrexate, 0.25 mg kg⁻¹ body weight per week in three divided doses given at 12-h intervals, have been effective in the author's experience when given to patients who do not respond adequately to UDCA. However, the efficacy of combination therapy (UDCA, colchicine, and methotrexate given together) has not been proved in randomized placebo-controlled trials.

Initiating treatment early in the course of PBC is important because medical therapy is less likely to help once cirrhosis and portal hypertension develop. Liver transplantation is the only effective treatment in patients with clinically advanced disease. The author's current approach is based on the observation that the response to medical treatment in PBC varies among patients. Treatment is initiated with UDCA. Colchicine is added if patients have not responded adequately to UDCA after 1 year. Methotrexate is added if patients have not responded fully to the combination of UDCA and colchicine after another year. An adequate response to treatment consists of resolution of pruritus, a decrease in serum alkaline phosphatase to values that are <50% above normal, and improvement in liver histology. Methotrexate is discontinued after 1 year if patients fail to respond to it. Patients are then maintained on UDCA and colchicine.

Liver transplantation

Liver transplantation has improved the survival of PBC patients with cirrhosis and liver failure. Patients who are candidates for liver transplantation are those with cirrhosis and (1) persistent

jaundice that is unresponsive to medical treatment, (2) ascites, (3) bleeding from esophageal varices, (4) hepatic encephalopathy, and/or (5) intractable pruritus. One-year survival after liver transplantation is greater than 90% in most transplant centers. Recurrence of PBC after liver transplantation occurs in about 10% of patients after 5 years and in 20% of patients after 10 years. Recurrence is more common if tacrolimus is used as an immunosuppressive agent rather than cyclosporine. We have observed that the treatment with UDCA and colchicine has decreased serum levels of bilirubin, alkaline phosphatase, ALT, and AST and has improved liver histology in patients with recurrent PBC.

Prions of Yeast and Fungi: Proteins Acting as Genes

R B Wickner, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Inc.

Glossary

Amyloid A filamentous form that many proteins can assume, characterized by high β -sheet content, protease-resistance, and yellow-green birefringence on staining with Congo red.

Chaperone A protein that aids the folding (or refolding or renaturation) of another protein.

Prion A protein that transmits a trait or disease without the need for an accompanying nucleic acid.

Prion domain Part of a protein that determines the prion properties of the full protein.

Yeast and Fungal Prions: Genetic Criteria

The word 'prion' means an infectious protein, by whatever mechanism. This idea arose from studies of the transmissible spongiform encephalopathies (TSEs) of mammals, believed to be due to an infectious form of a protein called 'PrP'. Two nonchromosomal genes of *Saccharomyces cerevisiae*, called [URE3] and [PSI⁺], were identified as prions, because their unusual genetic properties were inconsistent with their being nucleic acid replicons, but were just what one would expect for a prion (Figure 1). First, each could be efficiently eliminated (cured) from the cells, but, from the cured cells, could again arise, at low-frequency, cells carrying the nonchromosomal gene. Second, overproduction of the normal form of the protein was shown to increase the frequency with which the prion form arose *de novo*. In addition, it was the protein whose overproduction induced the appearance of the nonchromosomal gene, neither the RNA nor the gene in high copy number. Finally, the chromosomal gene encoding the protein was, of course, necessary for the propagation of the prion, but the phenotype of mutants in the chromosomal gene was the same as that in the presence of the prion.

Known Prions of Yeasts and Fungi

[URE3] has each of these properties as a prion of the Ure2 protein, a regulator of nitrogen catabolism in yeast. [URE3] cells are inappropriately derepressed for the enzymes and transporters needed for the assimilation of poor nitrogen sources. Similarly, [PSI] has the properties expected of a prion of the Sup35 protein, a subunit of the translation termination factor. [PSI⁺] cells show increased rates of read-through of termination codons (nonsense suppression). A prion of *Podospora anserina*, called [Het-s], is unique in performing a function for this fungus, being required for an antiviral defense mechanism called 'heterokaryon incompatibility'. A third *S. cerevisiae* prion, called [PIN⁺], was discovered by its ability to promote the *de novo* development of the [PSI⁺] prion and is an altered form of Rnq1p. While [URE3] and [PSI⁺] make their presence known by the absence of the normal form of Ure2p and Sup35p, respectively, both [Het-s] and [PIN⁺] produce a phenotype by the presence of the abnormal forms of HET-s and Rnq1p, respectively, similar to the case with the mammalian

TSEs. Swi1p and Cyc8p, two transcription regulatory proteins, were suspected to be capable of prion formation, because, not only do they have Q/N-rich domains similar to the prion domains of Ure2p and Sup35p, but the overproduction of either protein mimics the Pin ([PSI]-inducibility) effect of the [PIN] prion, resulting in the rare seeding of Sup35p to form the [PSI] prion. Mot3p was found to form a prion by studying proteins with Q/N rich domains. [ISP⁺] is an intranuclear prion of the transcriptional regulator Sfp1. It was then found that the full-length Mca1 protein, a metacaspase homolog, could be a prion. Careful studies showed that each could indeed form a prion as judged by the three genetic criteria discussed above.

Prions do not have to be based on self-propagating amyloids. The [BETA] prion is simply the active form of yeast vacuolar protease B (Prb1p). This protease is synthesized as an inactive precursor protein, and under certain circumstances, its active form is required for the processing of the inactive precursor to the active form by proteolytic cleavage. While having no connection with amyloid, this prion has all of the same genetic properties and is indeed an infectious protein. The crippled growth non-Mendelian genetic element of *P. anserina* may likewise be a prion based on self-action of a set of MAP kinases.

Prion Domains and Functional Domains

In Ure2p and Sup35p prion proteins, an N-terminal segment is responsible for the prion properties of the protein, while the normal functions of the protein are carried out by both the N-terminal and C-terminal domains (Figure 2). The prion domain can propagate the prion completely independent of the remainder of the protein, and can even confer prion properties if fused to unrelated reporter protein. The prion domain of Ure2p is necessary for the stability of the protein against degradation, while the C-terminal domain is the nitrogen regulation domain. The Sup35p prion domain functions normally in the degradation of the 3' polyA structure of all messenger RNAs (mRNAs), and is thus necessary for normal mRNA turnover, while the C-terminal domain functions with Sup45p in translation termination. The HET-s protein, Rnq1p, Swi1p, and Cyc8p also have special domains responsible for their prion properties.

Figure 1 Genetic properties identify prions. Cells cured of a prion can give rise to cells again carrying the prion (top). Overproduction of the prion protein increases the frequency with which the prion arises (middle). A mutant in the prion protein gene can have a similar phenotype to the presence of the prion because both lack the normal form of the protein (bottom). Here, the phenotype of prion or mutant is the ability to take up ureidosuccinic acid (USA), because Ure2p normally inhibits transcription of *DAL5*, which encodes a transporter capable of taking up USA. Phenotypes are shown at the bottom as USA+, or USA-.

Except for HET-s and PrP, the prion domains are all rich in asparagine or glutamine residues, and these runs of N or Q are important for the prion properties of the proteins. However, neither the HET-s protein nor mammalian PrP have regions rich in N or Q (Figure 2). The N-, Q-rich prion domains of Ure2p, Sup35p, and Rnq1 resemble the polyQ of Huntingtin whose amyloid formation is the central event in Huntington's disease.

Yeast, Fungal Prions [PSI⁺], [URE3], [PIN⁺], and [Het-s] Are Self-Propagating Amyloidoses

Amyloid is a special form of protein structure that is characteristic of a number of human diseases. Amyloid is a filamentous structure high in β -sheet content, with β -strands oriented perpendicular to the long axis of the filaments. Amyloid filaments display a characteristic yellow-green birefringence on staining with the aromatic dye Congo red and are partially resistant to protease digestion, probably reflecting their very stable β -sheet structure. Demonstration of aggregation is always simpler than that of amyloid structure, but it is evident that not all aggregates are amyloid. Amyloid formation by the A β peptide is the central event in Alzheimer's disease,

while amyloid of amylin is a prominent feature of late-onset diabetes. Parkinson's disease features intracellular amyloid formation by α -synuclein, and amyloid of serum amyloid A protein is a complication of many long-term infectious and inflammatory processes.

Sup35p, Ure2p, and HET-s each form amyloid *in vitro*. Moreover, the characteristics of the amyloid formed and the requirements for its formation closely reflect the corresponding properties and conditions of prion formation *in vivo*. For example, extracts of [PSI⁺] cells can prime the formation of amyloid by Sup35p much better than can extracts of normal cells. The prion domain of Ure2p induces amyloid formation by the full-length native Ure2p *in vitro* just as the prion domain produced *in vivo* induces *de novo* generation of the [URE3] prion. Indeed, filaments of Ure2p and Sup35p have been visualized specifically in [URE3] and [PSI⁺] cells, respectively. Most important, the amyloid filaments formed *in vitro* from recombinant HET-s, Sup35, Ure2, or Rnq1 proteins are highly infectious for yeast, transmitting the corresponding prion to the cells.

The mechanism by which amyloid formation inactivates Ure2p is apparently not by a conformational change of the nitrogen regulation domain of the molecule. For example, the glutaredoxin activity of the nitrogen regulation domain is unaffected by amyloid formation, suggesting that being

Figure 2 Prion domains of Ure2p, Sup35p, Rnq1p, and HET-s. While the prion domains of Ure2p, Sup35p, and Rnq1p are rich in N and Q, that of HET-s is rich in neither. Normal functions of the prion domains of Sup35p and Ure2p have been identified.

Figure 3 The in-register parallel β -sheet architecture of the prion domains of Sup35p, Ure2p, and Rnq1p. Each residue forms a line along the long axis of the filaments (white circles may be, e.g., Val35 of each molecule). Such rows of Asn or Gln residues form a line of peptide-like hydrogen bonds (the ‘beta zipper’). A row of Ser or Thr residues can form inter-residue bonds as well. A row of Leu, Val, Ile, Phe, Tyr, or Trp residues can have hydrophobic interactions along the fiber. These interactions force the new monomer (yellow) to assume the same structure as the molecule on the end of the fiber (red). This templating results in inheritance of structure, just as DNA templating results in inheritance of sequence.

in the amyloid filament sterically blocks access to binding Gln3p (the target of Ure2p action) or imposes a diffusion limitation.

The structures of the amyloid filaments have been analyzed using solid-state nuclear magnetic resonance (NMR). Amyloid of the HET-s protein is a β -helix, with each molecule making two turns of the helix. The Sup35, Ure2, and Rnq1 prion domains each form amyloids with an in-register parallel β -sheet architecture (Figure 3). This in-register parallel β -sheet architecture can explain how a single protein sequence can transmit its conformation to another molecule, and how any of several such conformations (prion variants) can be stably propagated by the same protein sequence. The sheet is folded along the long axis of the filament, and it is proposed that different locations of the folds, or different extents of the beta sheet structure along the sequence, can produce different variants. The in-register parallel β -sheet architecture allows proteins to act as a template to transmit their

structure, in analogy to the ability of DNA strands to template their sequence.

[PSI] and [URE3] Are Diseases, but [HET-s] Carries Out a Normal Function

Amyloidoses of humans are generally associated with disease states, and the TSEs, in particular, are uniformly fatal. However, the Pmel17 melanosome protein forms amyloid filaments that are involved in melanin biogenesis, and amyloids on the surface of bacterial and fungal cells function in adhesion and cell protection. The [URE3] prion is associated with slow growth under most culture conditions. [PSI⁺] and [PIN⁺] do not confer any consistent phenotype on otherwise normal cells, although over half of [PSI⁺] variants make cells very sick or dead. Searches by three groups for [PSI⁺] in wild strains

have failed to find it, supporting the notion that it is a disease, like the mammalian counterparts. The Ure2 and Sup35 prion domains have normal functions unrelated to prion formation, indicating that they are not conserved for the purpose of forming a prion. Indeed, prion-forming ability is not conserved, even within *S. cerevisiae*, where a quarter of wild isolates in one study have a large deletion in their Sup35 prion domain such that they cannot form a prion. Furthermore, one species of *Saccharomyces* has a Ure2p that also cannot form prions. The prion domains of Sup35 and Ure2 of *Saccharomyces* species have diverged much more rapidly than have the other parts of these molecules. Because prion propagation requires self-templating of peptides with identical sequence, this divergence has the effect of partially blocking prion transmission, and, as has been suggested for the M/V polymorphism at residue 129 of human PrP, this divergence may have been selected because it provides protection from the harmful effects of catching a prion.

A colony of a filamentous fungus is not a pile of cells (as in yeast), but rather a syncytium – cells connected by cytoplasmic bridges. When two compatible colonies of *Podospora* or other filamentous fungi grow together, they fuse cellular processes (hyphae) thereby joining the two colonies into one, called a ‘heterokaryon’. This allows the colonies to share nutrients, but has the danger that a virus infecting one will spread by cytoplasmic mixing throughout the other. To minimize this risk, filamentous fungi have a system, called ‘heterokaryon incompatibility’, which tests for identity between the partners at about a dozen polymorphic chromosomal loci. Nonidentity of alleles at a single locus is sufficient to abort the fusion process and a barrier to further fusion is formed. Most of these *het* loci are genetically unremarkable. The *het-s* locus of *Podospora* can have either of two alleles, *het-s* or *het-S*. A colony with the *het-s* allele is only properly incompatible with a *het-S* colony if the HET-s protein is in an amyloid form. This amyloid form is infectious and is the [Het-s] prion. The HET-S protein, which differs by only 14 amino acid residues from the HET-s protein, does not form amyloid, and residue 33 is critical in this difference.

Thus, the [Het-s] prion is the (so far) unique case of a prion that is necessary for a normal function, heterokaryon incompatibility. Consistent with this view is the fact that most wild strains of *P. anserina* with the *het-s* allele carry the [Het-s] prion. However, [Het-s] also mediates a meiotic drive system, in which the *het-s* allele is preferentially inherited in *het-s* X *het-S* crosses as a result of lethality of *het-S* [Het-s] spores. Thus, the [Het-s] prion may ultimately prove to be a disease like the yeast prions.

Prion Generation

[PIN⁺] was discovered as a nonchromosomal gene whose presence was necessary for the efficient induction of the *de novo* appearance of [PSI⁺] by overexpression of Sup35p. [PIN⁺] was found to be a prion of the Rnq1 protein, which had already been shown capable of a self-propagating aggregation *in vivo*. In fact, [URE3] is also capable of [PIN⁺]-like activity. This showed that one prion could promote the generation of another. This may be because all of these prions

([PSI⁺], [PIN⁺], and [URE3]) are based on amyloid of asparagine-glutamine rich segments. Although cross-priming of polymerization is not as efficient as self-priming (the usual propagation reaction), it is far more efficient than the truly spontaneous development of a prion. A similar, though weaker, effect of [PIN⁺] on [URE3] generation has also been observed.

Prion generation is also diminished by the Hsp70-group chaperones Ssb1p and Ssb2p. Both are ribosome associated, and are believed to help nascent peptides fold properly. It will be of great interest to understand the mechanisms by which Ssb’s block prion formation.

Chaperones and Prion Propagation

Chaperones play a central role in the propagation of yeast prions. Hsp104 is a disaggregating chaperone critical in the cellular reaction to heat shock, and either increasing or decreasing its level adversely affects propagation of [PSI⁺]. Amyloid aggregates are clumpy and may all remain in one of the daughter cells if they form a single lump in the mother cell. Modest levels of Hsp104 carry out the partial fragmentation of these filaments insuring that both daughter cells receive one or more seeds. Each of the other yeast amyloid-based prions likewise requires Hsp104 for propagation, but only [PSI⁺] is cured by Hsp104 overproduction. The mechanism of curing by Hsp104 overproduction is not known, but may be an effect on segregation of amyloid to daughter cells. Inhibition of Hsp104 by mM concentrations of guanidine cures all the amyloid-based yeast prions.

Different Hsp70s and Hsp40s have positive and negative functions with different prions. For example, overexpression of the Hsp40 protein, Ydj1, can cure [URE3] by its interaction with Hsp70s, and the Hsp40 Sis1p is needed by all prions tested. In spite of their close homology, one cytosolic Hsp70 promotes one prion while inhibiting another. Clearly, the detailed interactions of each prion with chaperones will be different, and this remains an important area to investigate. There is circumstantial evidence for a role of chaperones in the mammalian TSEs, but direct evidence has so far been limited to the yeast systems.

The importance of the discovery of the role of chaperones in yeast prions goes far beyond these systems and even the mammalian prion diseases. Amyloidoses are common (almost universal) diseases of old age, and one suspects that one of the primary roles of the heat-shock proteins is to defend against amyloid formation. It will be critical to learn how these systems can be marshaled to contend with these otherwise largely intractable human amyloidoses. A screen for chemical agents that cure yeast prions has turned up two candidates that also cure tissue culture cells of scrapie. These two compounds act on a ribosomal chaperone activity. It may be possible to extend this approach to finding general anti-amyloid drugs.

Conclusions

The ability of proteins to bear hereditary information recalls the earlier discovery by Sonneborn of cortical inheritance in *Paramecium*, in which the surgically altered arrangement of

cilia on the surface of the cell was shown to be faithfully inherited by the progeny of the original cell. Self-propagating protein structures in the former case are closely analogous to self-propagating organellar structures in the latter. Efforts to find other self-propagating organellar structures have not yet met with any clear successes, and the mechanisms operating in the cortical inheritance phenomenon have not yet been elucidated.

There are doubtless many prions because evolution is not a finished job. As there are useful (non-prion) amyloids, there are likely to be useful prions (perhaps [Het-s]), but which, if any, is not yet certain. Retroelements are selfish parasites, but they are DNA, and cells may occasionally be selected in which a particular retroelement has been harnessed to do the cell's work. This does not diminish their primary role as parasites.

Most of the prions discussed in this article appear to be based on the self-propagating amyloid of the corresponding protein. Of course, most amyloidoses are not prions, although nearly all have been shown to be self-seeding *in vitro*. Prion propagation requires not only expansion of amyloid within one individual cell or compartment, but also a mode of transmission. It is clear in several systems that fully formed amyloid is the infectious protein form, refuting suggestions that only some oligomer intermediate is the infectious material, although it is evident that the shorter the fiber, the higher the ratio of growing ends to mass of material.

The direct parallels between these yeast, fungal, and mammalian prions and amyloidoses have opened new areas for investigation of these very difficult human diseases.

The Prion as an Unprecedented Agent

The discovery of prions was inseminated by the research on the agent of the scrapie disease in sheep. Although transmissibility of the scrapie agent was suggested already 250 years ago, it was shown by inoculation experiments in sheep not until 1936 by J. Cuiil  and P. J. Chelle. Searching for a virus, however, did not lead to the detection of typical viral features; instead, highly enigmatic properties of the agent were demonstrated, such as the absence of particles in the electron microscope, no immune response during the infection, and high resistance of the agent against chemical and physical treatment. As early as 1966, Tikvah Alper and her colleagues concluded from inactivation studies using ionizing and ultraviolet (UV)-irradiation that the target size of the scrapie infectious agent of 50–150 kDa is too small for a virus, and the inactivation spectrum is more characteristic of a protein. In the following, Stanley B. Prusiner performed systematic analyses using not only chemical and physical but also enzymatic procedures. He summarized the results in two groups: (1) procedures which modify or destroy nucleic acids do not abolish scrapie infectivity and (2) procedures which modify or destroy proteins abolish infectivity. Many researchers discussed the scrapie agent as an unconventional virus but Prusiner came to the conclusion that the agent could not be a virus but a novel and unprecedented proteinaceous type of an agent, which he termed ‘prion’ (proteinaceous infectious particle).

As a major component of the prions a hydrophobic and, in mild detergents, insoluble protein of 33–35 kDa could be highly enriched. In a collaborative research project of the laboratories of Prusiner, L Hood, and Ch. Weissmann using the Syrian hamster as the experimental animal, the protein was cloned and shown to be a host-encoded protein, later called ‘prion protein (PrP)’. In a similar approach, Bruce W Chesebro and colleagues identified the corresponding protein in mice.

The prion protein from infectious material is partially resistant to degradation by proteinase K; it is N-terminally truncated at amino acid 89/90 leading to PrP 27–30, which retains full infectivity. The prion protein was identified as encoded in the host genome, and the protein was found indeed also in the noninfected organism. It is, however, very sensitive to proteinase K digestion, so that a clear biochemical distinction between two isoforms of the prion protein could be drawn: the cellular prion protein PrP^C in the noninfected organism, and the scrapie isoform PrP^{Sc} as the major component of the purified agent. It should be emphasized that proteinase K resistance of PrP was used as the first biochemical marker for infectivity, and often PrP^{Sc} and PrPres (for resistance) were used synonymously. Later, however, it was shown that infectivity and proteinase K resistance do not correlate in all cases; therefore, PrP^{Sc} is used for the property of infectivity and PrPres for proteinase K resistance, respectively.

Properties of the Two Isoforms of PrP

In addition to PK-resistance, more parameters were identified characteristically different for PrP^C and PrP^{Sc}. They are listed in [Table 1](#). Of particular relevance in the context of the scrapie history is the highly aggregated state of PrP^{Sc} because it is the physico-chemical basis of the resistance of prions to proteinase K degradation and deactivation procedures.

PrP was available in large amounts only when expressed recombinantly in *Escherichia coli*; when conditions were established (low pH) to solubilize PrP in high concentrations, the molecular structure of PrP in the noninfectious form could be solved by Kurt W  thrich and his co-workers applying high resolution nuclear magnetic resonance (NMR) spectroscopy. The structure is shown schematically in [Figure 1\(a\)](#). The C-terminal half of the molecule (residues 125–231) is folded in a well-defined globular structure comprising three α -helices and a short antiparallel β -strand, whereas the N-terminal half is more or less flexible. The globular part of the structure was confirmed by X-ray crystallography. Under more physiological conditions like neutral pH, low concentration of lipids and detergents, or membrane attachment, PrP tends to form dimers with additional secondary structure of the amino acids 90–125.

The insolubility of PrP^{Sc} prevented so far its structural determination with molecular resolution. A combination of molecular dynamic calculations, fiber diffraction studies, and biochemical data from chemical cross-linking, ligand accessibility, etc., led to a structural model (cf. [Figures 1\(b\)–1\(d\)](#)) which, however, should be regarded as preliminary. The model clearly reflects the fibrillar structure as known from electron microscopy of prion rods, and the intermolecular interactions are established by stacks of parallel β -helices.

The Prion Model

The concept of prions for scrapie infectivity was under debate for many years, and the unusual resistance against deactivation was interpreted by many researchers in terms of unconventional viruses or so-called virinos possessing only a very small not yet detected nucleic acid. Quantitative analysis by Prusiner, Riesner, and co-workers of nucleic acids possibly essential for scrapie infectivity resulted in the determination of a limit, that is, that less than one nucleic acid molecule with more than 20 nucleotides was present in one infectious unit; consequently viral or viroid-like nucleic acids could be excluded from being crucial for scrapie infectivity. Also, the direct evidence for the proteinaceous nature of the agent was broadened continuously during the last 20 years and particularly the generation of synthetic prions (cf. below) can be regarded as an experimental proof so that we consider at present only the prion concept as

valid for scrapie infectivity. A simple form of prion amplification is depicted in **Figure 2(a)**. PrP^C is expressed from a nuclear single copy gene and presented as a glycolipid-anchored protein on the outer cell membrane. If it comes into contact – in a direct or indirect manner – with PrP^{Sc}, it is enforced to switch over into the PrP^{Sc}-conformation. Breaking of the oligomeric or polymeric PrP^{Sc} generates more and new attachment and conversion sites for PrP^C leading to exponential growth of PrP^{Sc} subunits in prion particles. In summary, multiplication of prion infectivity is modeled by continuous synthesis of PrP^C and induced conformational conversion into PrP^{Sc}.

Table 1 Isoforms of the prion protein

Cellular isoform (PrP ^C)	Scrapie isoform (PrP ^{Sc})
Not infectious	Infectious
α -Helical	β -Sheet-rich
Monomer	Aggregated
Soluble (in mild detergents)	Insoluble
Proteinase K sensitive	Proteinase K resistant

Conformational Transitions and Synthetic Prions

The conformational transitions of PrP were studied in order to simulate the transition of the cellular isoform PrP^C into the pathogenic isoform PrP^{Sc}. Quite different conversion systems have been applied, among them lowering the pH, adding fairly high concentrations of denaturants like urea and GndHCl, or low concentrations of the detergent sodium dodecyl sulfate (SDS). In **Figure 3** the SDS conversion system is shown. By lowering the SDS concentration from 0.2%, which is still submicellar, to 0.01% or after washing out SDS, different conformational states were established; from monomeric partially denatured α -helical, via dimeric renatured α -helical and oligomeric β -sheet-rich to an highly aggregated β -sheet-rich but polymorphic state. By adding 0.15 M NaCl, an intermediate, partially denatured state can be established from either the dimeric α -helical or the oligomeric β -sheet-rich state. This intermediate state is essential because after several weeks of gently shaking, fibrils are formed spontaneously. If small amounts of prions are added as seeds, fibrils are formed within hours depending upon the concentration of prion seeds and PrP substrate. The kinetics can be described quantitatively

Figure 1 Structures of the prion protein. (a) Solution structure of the prion protein (90–231) from Syrian Goldhamster, (b) model for monomeric PrP^{Sc}, (c) trimeric PrP^{Sc}, and (d) PrP^{Sc} fibril.

Figure 2 Models for prion propagation and amplification. (a) PrP^C is expressed from a single copy nuclear gene and attached via a glycolipid-anchor to the outer cell membrane. Upon contact with PrP^{Sc}, PrP^C adopts conformation of PrP^{Sc}. (b) Mechanistic model of seeded fibrilization. D, degradation; B, breakage; E, elongation; λ , synthesis of monomeric PrP; δ , degradation of monomeric; n , minimal size of an oligomer active as seed.

Figure 3 *In vitro* conversion of PrP. Dilution of SDS causes a structural shift from monomeric PrP into amorphous PrP aggregates. Addition of sodium chloride favors transition into a high-energy intermediate promoting fibril formation.

in the mechanistic model of Figure 2(b). It should be noted that the method of protein misfolding cyclic amplification (PMCA) from Claudio Soto and co-workers follows a similar mechanistic model with the main difference, that growing of fibrils and breaking of fibrils are established experimentally in different steps.

Generation of infectivity from PrP which was never in contact with an infected animal or – even better – synthesized recombinantly in *E. coli* would be the ultimate proof for the prion model. In Prusiner's group, fibrils with recombinant PrP were generated spontaneously *in vitro* and used as an inoculum for transgenic mice. The mice became sick after a long

incubation time showing that the infectivity of the fibrils was very low, but from these mice the disease could be transmitted to wild-type mice with shorter incubation times. The conclusion of the experiments, that is, to generate infectivity with fibrillar PrP *de novo*, has been confirmed in the meantime by other groups using different procedures. In summary, it is possible today to produce synthetic prions.

Prion Strains

Host specificity of prions is determined primarily by the sequence of *Prnp*. Interpreting the prion model in a simplistic manner, one might expect that after inoculating prions from a foreign host and passing the species barrier the properties of prions in the new host are characterized only by the *Prnp* sequence of the new host. That is evidently not the case; by contrast, different phenotypes, so-called prion strains, are observed in one and the same host species, that is, genotype of *Prnp*. Prion strains are characterized by individual incubation times, spatial distribution of brain lesions, and behavioral peculiarities. Biochemical and biophysical analyses revealed also significant differences in properties like cleavage sites by PK-digestion, insolubility, resistance against deactivation procedures, and others. All of these features are transmitted over many passages. The molecular basis of the strain phenomenon is not clear. A second information molecule like a nucleic acid has been postulated many times but was never found experimentally. Rather, one has to assume that several pathogenic conformations like PrP^{Sc}₁ or PrP^{Sc}₂, and even more exist and induce again PrP^{Sc}₁ or PrP^{Sc}₂, respectively, in the next passage. It is not known on what level of structure hierarchy the strain-specific structural features are encoded. Without assuming additional cellular factors, one might suggest that subtle differences in the secondary structure are stabilized by the tertiary and, in particular, by the quaternary structure which then would act again as a structure-specific seed.

Physiology and Pathophysiology of PrP and Prions

The physiological role of PrP^C may be manifold and depends upon the cell type where it is expressed. Activities reported in the literature are: copper binding due to the His-containing N-terminal repeats with the consequences of copper endocytosis and homeostasis, superoxide dismutase (SOD) and antioxidant activity, furthermore signaling in different pathways, adhesion in conjunction with neural cell adhesion molecule (NCAM), and anti-apoptotic activity.

The pathophysiological role of PrP^{Sc} or prion infection is generally described as neurodegeneration. Vacuolar degeneration of the gray matter with PrP^{Sc} deposition is observed which led to the name spongiform encephalopathy. The location of pathological changes can be the cerebral or the cerebellar cortex depending upon the host species and the prion strain.

Molecular models of the pathology have to take into account both PrP^C and PrP^{Sc}. The loss of function of PrP^C due to conversion into PrP^{Sc} is not very probable as primary pathological event because transgenic PrP^{0/0} mice, that is, with knocked out PrP gene, do not show symptoms. Overexpression

of PrP^C, however, can lead to disease although not a typical prion disease. Therefore, one has to assume a toxic effect of PrP^{Sc}, but at present it is not clear whether intra- or extracellular PrP^{Sc} deposition itself or its labile and soluble intermediates or even its interaction with PrP^C is the primary pathological event. The molecular and cellular pathways leading to neurodegeneration are present-day themes of active research and deserve particular attention because of the general relevance for protein misfolding diseases. Among the afflicted cellular activities are apoptosis, endosomal–lysosomal activity, complement activation, and synaptic and dendritic function, without claiming completeness.

Scrapie Prions: The Transmissible Archetype of Protein Misfolding Diseases

A somewhat simplified but logic line in research can be drawn from historic scrapie to present-day Alzheimer's disease research. The first step was the experimental transmission of scrapie in sheep as mentioned above. A clear step forward was the observation of William J Hadlow that the neuropathology, that is, the spongiform degeneration of the brain and plaque deposition, of scrapie in sheep and the Kuru disease among the Fore people in Papua New Guinea looked very similar. Carleton Gajdusek and colleagues had described the Kuru disease as transmissible and could transmit experimentally the disease to monkeys. Briefly later, it became evident that also the Creutzfeldt–Jakob disease (CJD) belongs to that group of disease. When the first cases of bovine spongiform encephalopathy (BSE) in Great Britain were identified as a new disease, it was soon recognized as a prion disease. Very enigmatic, however, remained the etiology of CJD, which can be transmissible, for example, as iatrogenic accidents, or sporadic or even familial. Only the development of the prion hypothesis by Prusiner delivered a unifying concept: (1) the gene of the prion protein *Prnp* could be identified in every host accessible to the disease; (2) differences in the sequence of *Prnp* are the molecular basis for the observed species barriers although not understood quantitatively up to now; and (3) all familial cases of CJD are 100% correlated with a mutation in *Prnp*. The prion amplification model of Figure 2(a) is in accordance with the assumption that a mutation in *Prnp* could facilitate the conversion which then would lead to amplification as in the transmissible case. The sporadic cases would represent the very rare event of a spontaneous yet thermodynamically possible switch from PrP^C to PrP^{Sc}, which then would be amplified. As the prion model is today generally accepted as a molecular model, the diseases mentioned so far are called 'prion diseases'. A list of the most common natural prion diseases is shown in Table 2. Experimental prion diseases were transmitted to mice, hamsters, and bank voles.

The protein folding conversion of PrP and its connection with a disease suggested similarity to other neurodegenerative diseases like Alzheimer's disease, Parkinson, Huntington, and others. In those cases, specific proteins – others than PrP – are pathologically refolded and lead to disease-associated aggregates. These similarities led to the general concept of protein misfolding diseases; some are listed in Table 3. One should note, however, that only the prion diseases are transmissible,

Table 2 Natural prion diseases

Disease	Host	Etiology
Scrapie	Sheep	Natural transmission
Creutzfeldt–Jakob disease	Humans	90% sporadic Transmissible Familial
BSE (bovine spongiform encephalopathy)	Cattle	Transmission from meat and bone meal
CWD (chronic wasting disease)	Deer Elk	Natural transmission

Table 3 Protein misfolding diseases (selected)

Disease	Protein	Manifestation	Organ
Prion	Prion protein	cf. Table 2	Brain
Alzheimer	Abeta Tau	Sporadic Genetic	Brain
Parkinson	α -Synuclein	Sporadic Genetic	Brain
Huntington	Huntingtin	Genetic	Brain
Type II diabetes	Amylin (IAPP)	Sporadic	Pancreas
Injection-localized amyloidosis	Insulin	Sporadic (iatrogenic)	Skin Muscles

whereas the sporadic and genetic etiology is common to most protein misfolding diseases. That was also the reason why only in prion research an experimental animal model was available which facilitated the research significantly. When, however, the other protein misfolding disease could be established in transgenic mice, which overexpressed the corresponding protein, a new quality of research in the general protein misfolding disease was introduced.

Applied Aspects

Epidemic and Diagnosis

About 200 000 cattle were afflicted during the BSE epidemic in the United Kingdom and to a much lesser extent in other countries. In 1996, it became evident that BSE can be transmitted to humans. The disease was manifested in humans as variant CJD, a particular strain of CJD, and about 200 victims had to be regretted. The peak of the BSE epidemic was 1992, that of variant CJD in 2000, and both have dropped since then to nearly not significant numbers. The source of the infection with BSE was contaminated meat and bone meal, that of variant CJD consumption of cattle products, most probable of those containing high proportion of brain material.

In order to fight against the cattle epidemic and, in particular, against the danger of human disease, there was an urgent need for diagnostic procedures. Initially, safety measures were taken by testing all cattle in the slaughterhouses older than 24 months. Later, the age limit was raised stepwise to 30, 36,

and 42 months; still, cattle with clinical signs are always tested before entering the food chain.

All commercial tests were based on the property of partial PK-resistance of PrP^{Sc} in contrast to complete PK-sensitivity of PrP^C. The tests were post-mortem analyses of brain material; different kinds of enzyme-linked immunosorbent assay (ELISA) tests and Western-blot tests were offered. In recent years, much effort is taken to develop *ante mortem* diagnostics with blood or blood fractions as test material. Most promising is the method of PMCA (cf. above) and single particle counting methods, but both methods are not in routine use yet.

Post-mortem diagnosis in humans is similar to that in animals, but only of neuropathological and not of therapeutic interest. As a reliable *ante mortem* test from body fluids is not available, a combination of surrogate markers, imaging procedures like the MRI of the brain and behavioral tests are used with, however, very limited success in the early and even less in the preclinical stages of the disease.

Therapy

In spite of the large effort of several research groups, no therapeutic drug is presently available or applied in a larger clinical trial. A few medical treatments in the orphan drug mode are carried out presently with quinacrine and tetracycline; both are drugs that are licensed for other disease treatments. The molecular approaches to develop new drugs are directed to block or revert the conversion of PrP^C to PrP^{Sc}, to inhibit the synthesis of PrP^C, or to prevent the initial contact of PrP^C and PrP^{Sc}.

Glossary

Processivity The ability of an enzyme to catalyze more than one turnover before releasing the product or the substrate.

Replicase Protein machinery that copies a strand of DNA. Chromosomal replicases typically contain a core polymerase, a processivity clamp, and a clamp loader.

Replisome Protein machinery that copies both strands of DNA. Replisomes include the replicase (polymerase, clamp, and clamp loader) as well as a helicase to unwind DNA. A priming activity is required for one strand.

Clamp and Clamp Loader Structures

Comparative structures of sliding clamps from bacteria, eukaryotes, and archaeal cells are shown in [Figure 1](#). Bacterial clamps, called β subunit, are homodimers, while eukaryotic and archaeal proliferating cell nuclear antigen (PCNA) clamps are homotrimeric. Regardless of their oligomeric state, all clamps have a pseudo-sixfold symmetric appearance based in the repetition of a domain of similar folding pattern. Thus, the protomers of dimeric clamps are composed of three repeated domains and the protomers of trimeric clamps are comprised of two repeated domains. This architectural similarity among all clamps suggests that the sliding clamp evolved early, and was present in the last common ancestor before cells diverged into the three different domains of life. The same can be said for the clamp loader.

The structure of clamp loaders from *Escherichia coli* and yeast has been solved to high resolution ([Figures 2\(a\)](#) and [2\(b\)](#)). In each case, the five subunits essential for clamp loader function are arranged in a circular spiral shape. The clamp loader of *E. coli*, referred to as γ complex, has two additional subunits (χ and ψ) that are not required for clamp loading, although they facilitate the reaction. The five clamp-loading subunits consist of three γ subunits and one each of the δ and δ' subunits, all of which are members of the AAA+ family of ATPases (ATPases associated with diverse cellular activities). Only the γ subunits contain ATP-binding sites. The γ , δ , and δ' subunits are composed of three domains; the two N-terminal domains contain the AAA+ region of homology, while the C-terminal domains are tightly packed together and form the major pentameric contacts.

The recent crystal structure of $\gamma_3 \delta \delta'$ bound to a primed DNA reveals details of how it interacts with a primed site in a structure specific, yet sequence-independent, fashion ([Figure 2\(a\)](#)). The N-terminal domains (domain 1) are arranged in a spiral that matches the pitch of duplex DNA and they form attachments to the phosphodiester backbone of the template strand of the duplex. The circular arrangement of the subunits thus forms a central chamber into which duplex DNA fits. The C-terminal domains (domain 3) form an uninterrupted collar which prevents DNA from continuing in a straight path. However, there is a distinct gap

in the side of the clamp loader located between the AAA+ domains of the δ and δ' subunits, and the single-strand (ss) DNA bends to exit through this gap. The sharp bend required to exit the central chamber of the clamp loader cannot be accommodated by a rigid duplex, and it is this requirement for a sharp bend that confers structure-specific binding to a primed site by clamp-loading machines. Specifically, the ssDNA portion of the primed site has the requisite flexibility needed to make the sharp bend for exit of the DNA from the central chamber.

The structure of the eukaryotic clamp loader, referred to as replication factor C (RFC), has been solved in complex with the PCNA clamp ([Figure 2\(b\)](#)). Unlike the five clamp-loading subunits of the bacterial clamp loader, each of the five RFC subunits is encoded by a distinct gene. However, each RFC subunit is an AAA+ family member and shows homology to the bacterial clamp loader subunits. Accordingly, RFC is structurally and functionally similar to *E. coli* γ complex. The PCNA clamp binds to the N-terminal domains of RFC subunits and a model of DNA bound to the RFC–PCNA complex indicates that DNA located in the central chamber of RFC is positioned to pass through the center of the PCNA ring. This satisfying structural arrangement suggests that, upon opening the clamp, the clamp loader will bind a primed site in a way that positions DNA through the clamp.

Biochemical studies have shown that ATP binding is sufficient for clamp opening and DNA binding in both bacterial and eukaryotic systems. ATP hydrolysis is required for clamp closing and this ejects the clamp loader from the DNA, leaving the clamp topologically linked to DNA as illustrated in [Figure 2\(c\)](#). The RFC–PCNA structure in [Figure 2\(b\)](#) contains ATP γ S, yet PCNA remains closed in the RFC–PCNA structure. Presumably, this closed state of PCNA is due to ATP site mutations in RFC that prevent hydrolysis during crystal growth. The PCNA ring interacts with three of the five RFC subunits because the N-terminal surface of the clamp loader is not flat, but instead assumes a spiral shape. Molecular simulation studies indicate that the PCNA clamp opens into a right-handed lock-washer configuration that may fit on the N-terminal spiral surface of RFC when the clamp is opened. A similar structure is implied by electron microscopy particle reconstruction studies of an archaeal RFC–PCNA–DNA complex.

Polymerase Switching on Clamps during Replication

All cells contain multiple DNA polymerases and repair factors that function with the sliding clamp. The fact that sliding clamps are homooligomers has given rise to the tool-belt hypothesis in which multiple polymerases attach to one clamp simultaneously. In fact, the binding of more than one protein to the same clamp has been demonstrated experimentally. However, the clamp can only accommodate one DNA template and therefore the different polymerases attached to the clamp must time-share for the single DNA template. The process by which different enzymes share, or switch, with one another is suggested by the crystal structure of *E. coli* β bound to a primed site (Figure 3). The structure shows that DNA passes through the ring at a sharp angle, $\sim 22^\circ$ relative to the C2 axis perpendicular to the plane of the ring. Both strands of the duplex are bound by residues on loops that project from the face of the clamp (see Figure 3(a)). The loops of only one of the two identical subunits of the β clamp can bind to DNA at a given time. Thus, the DNA likely isomerizes between the two protomers, and this DNA flipping from one protomer to another may provide the motions needed to switch the primed site among different polymerases attached to the same clamp as illustrated in Figure 4(a).

Experiments to address the use of different polymerases with the clamp have demonstrated that they can exchange with one another through an intermediate complex in which two DNA polymerases are bound to the same clamp. An early demonstration of polymerase switching utilized the phage T4 system in which mutant and wild-type T4 gp43 DNA polymerases traded places on the same clamp during ongoing replication. Similar studies in *E. coli* showed that two different polymerases, the Pol III replicase and Pol IV translesion bypass enzyme, simultaneously bind to β and trade places on the

DNA. The latter study demonstrated that when Pol III stalls, Pol IV takes over the primed site. Pol III recruits the primed site back from Pol IV under moving conditions.

Polymerase Exchange on Sliding Clamps during DNA Damage

One unexpected feature of the β -DNA structure is an interaction of the ssDNA at the primed site as illustrated in Figure 3(b). The ssDNA binds into a hydrophobic pocket on the surface of the clamp. The ssDNA is guided into the binding pocket by a channel lined with positively charged residues and by two conserved tyrosine residues that stack with nucleotide bases. This hydrophobic binding pocket is the same site to which DNA polymerases attach to the clamp. Therefore, it seems unlikely to be occupied by DNA while the clamp is functioning with the DNA polymerase. However, if a DNA polymerase dissociates from the clamp, this binding pocket may serve the function of a placeholder, helping to hold the clamp at the primed site where it can later be joined with a DNA polymerase (see Figure 4(b)). This placeholder action has been demonstrated in single-molecule studies and may be useful during polymerase exchange reactions in which the clamp is unoccupied for a period of time during the switching process.

Recent experiments address the response of replication forks to high levels of translesion (TLS) polymerases which are induced inside cells upon DNA damage. DNA damage in *E. coli* leads to an SOS response in which many different proteins are induced to high levels. These proteins generally help the cell to cope with DNA damage. Among the earliest proteins to be induced are Pol II and Pol IV, TLS polymerases that function with the β clamp to extend DNA over various DNA blocks. An *in vivo* study showed that induction of Pol IV

Figure 3 Interactions of the β clamp with DNA. (a) Interaction of *E. coli* β with double-strand DNA of a primed template reveals DNA is highly tilted as it passes through the ring. Residues R24 and Q149 are located on surface loops and these residues of one subunit bind both strands of DNA (R24 and Q149 are shown as a space filling representation). (b) Interaction of β with ssDNA at the primed site. The illustration depicts binding of the ssDNA to a surface pocket in β . The inset shows the detailed structure of ssDNA binding to the pocket. Tyrosines 153 and 154 stack with nucleotide bases. Adapted from figures 3(a) and 4(c) of Georgescu RE, Kim SS, Yurieva O, et al. (2008) Structure of a sliding clamp on DNA. *Cell* 132: 43–54.

Figure 4 Predicted functions of DNA interaction with the clamp. (a) The tilted DNA binds residues of one β protomer (see [Figure 3\(a\)](#)), yet these same residues are present on the other protomer of β . Thus, the DNA likely isomerizes from one protomer to the other, resulting in large movements of the primed template junction. These movements may facilitate switching of the primed site between different DNA polymerases bound to the same ring. (b) The ssDNA binding site may serve a placeholder role, holding β to a primed site if no DNA polymerase is bound to it. Adapted from Figure 7 of Yao NY and O'Donnell M (2008) Replisome dynamics and use of DNA trombone loops to bypass replication blocks. *Molecular Biosystems* 4: 1075–1084.

Figure 5 The replisome can morph into different architectures. (a) A replisome consisting of Pol III holoenzyme attached to DnaB, β clamps, and primase. Leading and lagging strand syntheses are coupled by the dimeric structure of Pol III holoenzyme. (b) Displacement of Pol III holoenzyme by TLS polymerases such as Pol II and Pol IV results in an uncoupled replisome. The TLS polymerases act in a distributive fashion by trading places on β clamps.

halts replication forks in a β -dependent fashion. *In vitro* studies reveal that both Pol II and Pol IV rapidly dislodge Pol III from β in the context of the moving replication fork, even in the absence of a DNA blocking lesion.

The fact that Pol III can be dislodged from the replication fork is somewhat surprising given the numerous interactions of the Pol III replicase with other components of the replication fork (Figure 5(a)). At a replication fork, Pol III is embedded in a large multi-protein complex referred to as Pol III holoenzyme, which contains two molecules of Pol III attached to one clamp loader. The clamp loader within Pol III holoenzyme contains τ subunits in place of the γ subunits. This is possible because both τ and γ are encoded by the same gene (*dnaX*). The τ subunit is the full-length product of the *dnaX* gene, while γ is truncated by a translational frameshift. The extra C-terminal 24 kDa in τ consists of two domains that appear to connect to the clamp-loading domains via a flexible linker. The C-terminal domains on the τ subunits are known to bind Pol III and also the hexameric DnaB helicase that encircles the lagging strand. The τ subunits also bind directly to DNA, further cementing Pol III holoenzyme into the replication fork. In addition, Pol III holoenzyme contains a subunit called χ that binds to SSB (single-strand binding protein), providing yet another point of contact between Pol III holoenzyme and the replication fork. These several contacts may be expected to hold Pol III to the replication fork.

Despite these several connections, Pol II and Pol IV are capable of rapidly taking over β clamps from Pol III on both the leading and lagging strands of the moving replication fork, as illustrated in Figure 5(b). Due to the slow speed of Pol II and Pol IV, the replication fork slows dramatically, from about 1000 basepairs (bp)/s to 10 bp/s (Pol II) or 1 bp/s (Pol IV) depending on which polymerase occupies the fork. In the cell, these slow-moving replication forks may give more time for DNA damage to be repaired by normal repair systems, thereby

diminishing the probability that a replisome will encounter a DNA lesion. Study of these slow replication forks reveal that the translesion DNA polymerases, Pol II and Pol IV, rapidly exchange on the clamp, and that the clamp is unoccupied some of the time. Thus, translesion polymerase action within the translesion replisome is highly distributive. Under these conditions, the β clamp-ssDNA interaction may come in very useful in the role of a placeholder for the β clamp.

Questions for Future Studies

It has been nearly 20 years since the circular nature of the *E. coli* β clamp, the first protein known to bind DNA topologically, was discovered. On the one hand, we know a great deal about the structure and function of DNA clamp processivity factors. On the other hand, their use by many different polymerases and repair factors has expanded the list of important questions about how these clamps function. In both bacteria and eukaryotic systems, the replicating polymerase can bind tight to its cognate sliding clamp, yet hop from one clamp to the next. This polymerase hopping mechanism was originally thought to function only on the lagging strand enabling extension of multiple Okazaki fragments by one DNA polymerase. However, recent studies suggest that polymerases hopping among clamps may be used as a general strategy to bypass other types of blocks, such as lesions or RNA polymerase. Further studies should elucidate if clamps circumvent barriers to replication by mediating polymerase hopping around the barrier. The detailed mechanism by which different polymerases recruit the DNA template while bound to a clamp with another polymerase is also still largely a mystery. Clamps can also be modified. The eukaryotic PCNA clamp is modified by ubiquitin in response to DNA damage; the function of this modification is not clear. Eukaryotes also possess alternative clamp

loaders, one of which loads an alternative clamp (911 clamp) onto a 5' single-strand/double-strand junction for activation of a kinase involved in the DNA damage checkpoint response. Clearly, many exciting questions about sliding clamp function remain for future studies.

Glossary

5-Lipoxygenase The oxygenase that converts arachidonic acid and related 20 carbon essential fatty acids to leukotrienes.

Aspirin A nonsteroidal anti-inflammatory drug that inhibits cyclooxygenase by acetylating an active site serine residue and blocking productive binding of arachidonic acid.

Cyclooxygenase Common name of the oxygenase enzyme that converts arachidonic acid and related 20 carbon essential fatty acids to prostanoids.

FLAP 5-Lipoxygenase activating protein, an accessory protein that is required for 5-lipoxygenase functioning in intact cells.

Leukotriene Those oxygenated derivatives of 20 carbon essential fatty acids formed through the action of 5-lipoxygenase and containing a conjugated triene system of double bonds.

Montelukast A drug used in the treatment of asthma that inhibits the binding of peptidoleukotrienes to the CysLT₁ receptor.

Prostanoid Those oxygenated derivatives of 20 carbon essential fatty acids formed through the action of prostaglandin endoperoxide H synthase.

Prostanoid Structures

Figure 1 shows the biosynthetic relationships among the prostanoids formed from AA. The letters following the abbreviation PGs indicate the nature and location of the oxygen-containing substituents present in the cyclopentane ring; the subscript indicates the number of carbon–carbon double bonds in the side chains. Greek subscripts denote the orientation of ring hydroxyl groups (e.g., PGF_{2α}). Prostanoids known as isoprostanes are formed from AA by nonenzymatic peroxidation and consequently contain many stereoisomers. Interestingly, the amounts of isoprostane metabolites in urine are greater than prostanoids formed enzymatically.

Prostanoid Biosynthesis

Eicosanoids are not stored in cells but are formed on demand in response to extracellular hormonal stimuli (e.g., bradykinin, angiotensin, and thrombin) that increase cell Ca²⁺ concentrations. Prostanoid formation requires three enzymatic steps: (1) mobilization of AA (or 2-arachidonylglycerol (2-AG)) from membrane phospholipids; (2) conversion of arachidonate (or 2-AG) to PGH₂ (or 2-PGH₂-glycerol); and (3) isomerization of PGH₂ (or 2-PGH₂-glycerol) to one of the major prostanoids by a terminal synthase. Mobilization of AA involves cytosolic phospholipase A₂ (cPLA₂) which translocates to the endoplasmic reticulum (ER) and nuclear membrane (NM) when intracellular Ca²⁺ concentrations rise and cleaves AA from a phospholipid on the cytosolic surface of the membrane. Newly released AA moves, methyl end first, to the luminal half of the bilayer where it enters the active site of a prostaglandin endoperoxide H synthase (PGHS) and is oxygenated to PGG₂ and its 15-hydroperoxyl group is then reduced to form PGH₂; PGHSs are also called cyclooxygenases (COXs) and there are two isoforms (PGHS-1 and -2; COX-1 and -2). Once formed, PGH₂ is isomerized by a synthase located in the ER

(e.g., TXA synthase and PGE synthase). Recently, 2-AG has been found to be converted to 2-PGH₂-glycerol by PGHS-2. This latter intermediate can be converted to the 2-prostanlyl-glycerol derivatives but not 2-thromboxane-glycerol. 2-AG itself is probably formed from phosphatidylcholine by phospholipase C and monoacylglycerol lipase.

PGHS Catalysis and Inhibition

Figure 2 is a model of the COX and peroxidase active sites of ovine PGHS-1. To initiate oxygenation of AA at the COX site, the heme group at the peroxidase site must first be oxidized by a hydroperoxide. This causes formation of an oxidized heme intermediate that is reduced by an electron from Tyr385, thereby generating a Tyr385 radical. This radical abstracts a hydrogen from AA so that it can react with oxygen (**Figure 1**). The guanidino group of Arg120 binds to the carboxylate group of AA.

PGHS-1 is a constitutive enzyme purified in 1975 and its cDNA cloning has been reported in 1988. PGHS-2 is an inducible enzyme discovered in 1991 as an immediate early gene product in phorbol ester-activated murine 3T3 cells and in *v-src*-transformed chicken fibroblasts. PGHS-2 contains a unique 18 amino acid insert near its carboxyl terminus that regulates the degradation of the protein. The reason for the existence of the two PGHS isoforms is not known. Each protein functions as a homodimer with a monomer mass of 72 kDa. PGHSs are integral membrane proteins which instead of having transmembrane helices have a cluster of four amphipathic helices that interact with only one face of the lipid bilayer.

PGHSs are inhibited by nonsteroidal anti-inflammatory drugs (e.g., aspirin, ibuprofen, and naproxen), which compete with AA for binding to the COX site of PGHSs. Prostaglandin synthesis mediated by PGHS-2 can be inhibited by anti-inflammatory steroids, which block the synthesis of PGHS-2 protein. Drugs called COX-2 inhibitors (e.g., celecoxib) target PGHS-2 specifically and are used as anti-inflammatory and analgesic agents.

Aspirin, acetylsalicylic acid, binds the COX site of PGHSs and acetylates Ser530 causing irreversible inhibition of PGHSs (Figure 2). Low doses of aspirin are used prophylactically to reduce coronary thrombosis; at low doses, aspirin inhibits PGHS-1 in platelets blocking thromboxane formation. PGHS inhibitors appear to reduce mortality from colon cancer.

PGHS-1 and PGHS-2 Gene Expression

There are separate genes for PGHS-1 and PGHS-2 located on different chromosomes. They have similar intron/exon structures

but the PGHS-2 gene is 8 kb and the PGHS-1 gene is 22 kb. Little is known about the regulation of PGHS-1 gene expression. PGHS-2 gene transcription can be induced by cytokines and growth factors that function through multiple response elements in the PGHS-2 gene promoter. There is much interest in this because of the potential role of altered PGHS-2 expression in carcinogenesis and inflammatory diseases.

PGH₂ Metabolism

Different cells form different prostanoids. PGE₂, PGD₂, PGF₂, PGI₂, and TXA₂ syntheses from PGH₂ are catalyzed by PGE, PGD, PGF, PGI, and TXA synthases, respectively; all of these enzymes catalyze isomerization reactions. PGF₂ formation involves a two-electron reduction of PGH₂. PGI and TXA synthases are cytochrome P-450s. PGE synthase is a member of the MAPEG family of transmembrane ER proteins and requires reduced glutathione for activity. There are two PGD synthases: a hematopoietic type is glutathione dependent and has been isolated from spleen and a lipocalin type is glutathione independent and occurs in brain.

Prostanoid Catabolism

The initial step in the inactivation of PGE₂ is oxidation of the 15-hydroxyl group to a 15-keto group catalyzed by 15-hydroxyprostaglandin dehydrogenase. Further catabolism involves reduction of the double bond between C-13 and C-14, β -oxidation, and ω -oxidation.

Prostanoid Actions

There are pharmacologically distinct receptors for each of the known prostanoids. In the case of PGE₂, four different prostaglandin E (EP) receptors have been identified and designated as EP1, EP2, EP3, and EP4 receptors. EP1 is coupled through G_q to the activation of phospholipase C, EP2 and EP4 are coupled

Figure 1 Biosynthesis of common prostanoids from AA.

Figure 2 Model of the cyclooxygenase and peroxidase active sites of the ovine PGHS-1.

via G_s to the stimulation of adenylate cyclase, and EP3 receptors are coupled via G_i to inhibition of adenylate cyclase.

EP3 receptors are involved in the development of fever, EP2 and EP4 function in bone resorption, and EP1 receptors are involved in chemically induced colon cancer. Prostanoids can activate some isoforms of peroxisomal proliferator-activated receptors (PPARs). PGI_2 can be involved in PPAR δ -mediated responses such as decidualization and apoptosis.

Leukotrienes and Lipoxygenase Products

Leukotrienes were discovered in 1979 during the search for the chemical structure of the "slow reacting substance of anaphylaxis." Leukotrienes are produced by the action of 5-lipoxygenase (5-LO) (Figure 3) which catalyzes both an oxygen insertion to form 5-HpETE and a dehydration reaction to form leukotriene A_4 (LTA_4). LTA_4 is converted to the biologically active leukotrienes LTB_4 and LTC_4 by LTA_4 hydrolase and LTC_4 synthase, respectively. LTB_4 is a potent chemotactic and chemokinetic agent for human polymorphonuclear leukocytes, whereas LTC_4 constricts specific smooth muscle (e.g., bronchial smooth muscle) and mediates leakage of vascular fluid in the process of edema. The formation of LTC_4 versus LTB_4 is controlled by the expression of LTA_4 hydrolase or LTC_4 synthase by specific cell types. For example, the human neutrophil expresses LTA_4 hydrolase and produces LTB_4 ,

whereas mast cells and eosinophils express LTC_4 synthase and produce LTC_4 .

5-Lipoxygenase

Human 5-LO (E.C.1.13.11.34) is a nonheme iron-containing protein of 673 amino acids. It catalyzes the abstraction of a hydrogen atom from C-7 of AA and insertion of O_2 at C-5 to generate 5(S)-HpETE (Figure 3). The LTA_4 synthase activity of 5-LO then catalyzes removal of 10 pro-R hydrogen atoms from 5(S)-HpETE through a second redox cycle and an internal rearrangement of double bonds to form LTA_4 . LTA_4 has a half-life of less than 10 s at pH 7.4. Purified 5-LO requires Ca^{2+} , ATP, fatty acid hydroperoxide, and phosphatidylcholine in addition to the AA and O_2 substrates. Ca^{2+} facilitates the association of 5-LO with internal membranes. The need for an increase in intracellular Ca^{2+} concentrations differentiates 5-LO from other lipoxygenases. 5-LO oxygenates AA at the nuclear member (NM). When Ca^{2+} concentrations increase in neutrophils and mast cells, 5-LO and cytosolic PLA $_2$ become associated with the nuclear membrane where another protein required for LTA_4 synthesis – 5-lipoxygenase activating protein (FLAP) – is found. In other cells 5-LO is constitutively associated with the NM, whereas in alveolar macrophages 5-LO is present in the nucleus. The drug zileuton inhibits 5-LO.

The 5-LO gene is large (c. 80 kb) and has 14 exons. It is on human chromosome 10. The human 5-LO gene promoter

Figure 3 Biochemical pathway of the conversion of AA into the biologically active leukotrienes. AA released from phospholipid by cPLA $_2$ is metabolized by 5-LO to 5-hydroperoxyeicosatetraenoic acid (5-HpETE) and leukotriene A_4 (LTA_4) which is then converted to LTB_4 by LTA_4 hydrolase or conjugated to glutathione to form LTC_4 by LTC_4 synthase.

contains Spl and EGR-1-binding sites at -88 to -212 bp upstream of the translation start site. Genetic polymorphisms in humans are found in Spl-binding sites.

5-Lipoxygenase Activating Protein

FLAP was discovered as a novel protein essential for leukotriene synthesis which was the target of an investigational drug from Merck (MK886). FLAP is an integral membrane protein of the NM containing 161 amino acids. The function of FLAP is unclear but it does bind AA analogs suggesting that it may transfer AA to 5-LO. LTC₄ synthase has 31% amino acid identity to FLAP with a highly conserved region putatively involved in AA binding.

LTA₄ Hydrolase and LTC₄ Synthase

LTA₄ hydrolase catalyzes the stereochemical addition of water to C-12 of LTA₄ to form the neutrophil chemotactic factor LTB₄. LTA₄ hydrolase contains 610 amino acids and one essential zinc atom. The enzyme is structurally related to zinc metalloproteases and exhibits protease activity; bestatin and captopril inhibit the enzyme. LTA₄ and LTC₄ synthases are found in many cells including those which do not contain 5-LO. It is believed that such cells can cooperate in LTB₄ and LTC₄ transcellular synthesis by transferring LTA₄ from one cell to another. LTA₄ hydrolase is localized in the cytosol. To metabolize the unstable LTA₄, LTA₄ hydrolase must either come in contact with the NM during LTA₄ formation or a carrier protein must transfer LTA₄ to LTA₄ hydrolase. The crystal structure of LTA₄ hydrolase has been determined.

LTC₄ synthase (E.C.2.5.1.37) conjugates reduced glutathione (γ -glutamyl-cysteinyl glycine) to LTA₄. LTC₄ synthase is located on the NM. The enzyme has significant sequence homology to microsomal glutathione-S-transferases and FLAP. LTC₄ synthase is found predominantly in mast cells, macrophages, eosinophils, and monocytes. MK-886, which interacts with FLAP, also inhibits LTC₄ synthase. The gene for LTC₄ synthase is located on human chromosome 5.

Leukotriene Metabolism

LTB₄ can be oxygenated to 20-hydroxy-LTB₄ by specific cytochrome P-450s of the CYP4F family. 20-Hydroxy-LTB₄ can be further metabolized to 20-carboxy-LTB₄ by CYP4F3 or to 20-oxo-LTB₄ by alcohol dehydrogenase then to 20-carboxy-LTB₄ by fatty aldehyde dehydrogenase. An alternative pathway involves an initial oxidation of the 12-hydroxy group to a 12-oxo moiety followed by reduction of the conjugated dienone and the 10,11 double bond. A secondary catabolic pathway, β -oxidation,

can occur from the C-1 carboxyl moiety of LTB₄ resulting in the loss of the C-5 hydroxyl group and from the 20-carboxy terminus of 20-carboxy-LTB₄. Individuals with genetic deficiencies in peroxisomal metabolism (Zellweger disease) that reduce β -oxidation or in aldehyde dehydrogenase (Sjogren-Larsson syndrome) excrete intact LTB₄ and 20-hydroxy-LTB₄. LTC₄ catabolism involves peptide cleavage reactions involving glutamyl transpeptidase and various dipeptidases to yield LTD₄ and LTE₄, both of which have biological activity. The sulfur atom of sulfidopeptide leukotrienes can be oxidized by reactive oxygen species. More specific metabolic processing of the sulfidopeptide leukotrienes includes ω -oxidation by cytochrome P-450 followed by β -oxidation from the ω terminus.

Leukotriene Biology and Leukotriene Receptors

LTB₄ functions in inflammatory processes through its chemotactic and chemokinetic affect human polymorphonuclear leukocytes. LTB₄ induces the adherence of neutrophils to vascular endothelial cells and enhances the migration of neutrophils (diapedesis) into extravascular tissues. The biological activity of LTB₄ is mediated through two specific G-protein-coupled receptors termed BLT₁ and BLT₂. LTC₄ and its peptide cleavage products LTD₄ and LTE₄ mediate bronchial smooth muscle contraction in asthma and cause edema. There are two G-protein-linked receptors for cysteinyl leukotrienes called CysLT₁ and CysLT₂. CysLT₁ is found in bronchial and intestinal smooth muscle; LTD₄ and LTC₄ activate CysLT₁. Montelukast, pranlukast, and zafirlukast inhibit the CysLT₁ receptor in humans. CysLT₂ receptors are abundant in the heart and in vascular endothelial cells.

Glossary

Gla The amino acid gamma-carboxyglutamic acid.

Hemophilia Any of several hereditary blood coagulation disorders in which the blood fails to clot normally.

Hemostasis The stoppage of blood flow characterized by vasoconstriction and the formation of a platelet plug and polymerized fibrin.

Platelet A small, non-nucleated, cell body found in the blood that functions to promote blood clotting.

Protease Any of various enzymes that catalyze the hydrolytic breakdown of proteins into peptides or amino acids.

Proteolysis The hydrolytic breakdown of proteins into smaller proteins, peptides, or individual amino acids.

Transglutaminase Any of various enzymes that catalyze the covalent linkage of protein-bound glutamine and lysine amino acid side chains.

Vitamin K A fat-soluble vitamin that promotes blood coagulation and prevents hemorrhage.

Warfarin A synthetic organic compound, derived from the natural product coumarin, that antagonizes the effect of vitamin K.

Zymogen The inactive precursor of an enzyme, converted into an active enzyme by proteolysis.

The biochemical pathways leading to thrombin formation are now well understood, as are the mechanisms by which thrombin promotes and modulates hemostasis. In response to vascular damage, thrombin is generated from an inactive precursor by a series of biochemical reactions collectively known as the coagulation cascade (Figure 1). Thrombin subsequently catalyzes a series of reactions that lead to platelet aggregation, fibrin polymerization, and, ultimately, feedback downregulation of the coagulation cascade itself (Figure 2). The enzymes involved in these pathways are structurally and functionally related to trypsin, the prototypical serine protease of the digestive system. However, in contrast to trypsin, the coagulation proteases are characterized by a complex modular architecture that facilitates interactions with one another, with other protein substrates, as well as with protein cofactors. These interactions serve to restrict the proteolytic reactions of the blood coagulation cascade to coagulation-promoting surfaces at sites of vessel injury.

The Coagulation Cascade

The Extrinsic Pathway

Almost since the 1960s, the coagulation cascade has been envisaged as a series of stepwise reactions in which inactive forms of serine proteases are converted to active forms by limited proteolysis in a process known as ‘zymogen activation’. The coagulation cascade is initiated when tissue factor, an integral membrane protein located in the tissue adventitia, is exposed to circulating blood following a vascular injury (Figure 1). The binding of tissue factor to factor VII or to the active serine protease factor VIIa (trace amounts of which circulate in the blood) initiates the extrinsic pathway of coagulation. The tissue factor–factor VIIa complex converts factors IX

and X to their active forms (IXa and Xa). Feedback amplification is achieved when inactive factor VII bound to tissue factor is converted to its active form (VIIa) by factors VIIa, IXa, and Xa, resulting in an enhanced generation of factor Xa. The factor Xa thus produced generates thrombin from its inactive form (prothrombin) in the presence of calcium, the nonenzymatic cofactor factor Va, and anionic phospholipid (primarily phosphatidylserine (PS)) exposed on the surface of activated platelets or other cells. Thrombin generated in the extrinsic pathway initiates an additional feedback amplification loop by generating factors Va and VIIIa by limited proteolysis. These surface-bound protein cofactors serve as scaffolds for the assembly of complexes that facilitate the production of factors Xa and thrombin (the Xase and prothrombinase complexes, respectively).

The Intrinsic Pathway

Thrombin enhances flux through the coagulation cascade by activating the intrinsic pathway of coagulation. In this arm of the cascade, thrombin generates factor XIa from its zymogen form (XI) by limited proteolysis. Factor XIa then generates factor IXa by a similar mechanism. The precise physiological role of the intrinsic pathway has been the subject of considerable debate, particularly because defects or deficiencies of factor XI are mild, and are associated with a form of hemophilia that is quite distinct from classical hemophilia. Bleeding due to factor XI deficiency is typically associated only with major surgery or trauma, whereas deficiencies of factor VIII (hemophilia A) or factor IX (hemophilia B) give rise to spontaneous soft tissue and joint bleeding. Thus, whereas the extrinsic pathway is required in most cases of vessel injury, the intrinsic pathway appears to be necessary for sustained thrombin generation in response to severe hemostatic challenges.

Figure 1 The blood coagulation cascade. Inactive cofactors and inactive (zymogen) forms of serine proteases are represented by gray circles. Active proteases are shown in green. Active protein cofactors are shown in purple. Phospholipid membranes are shown in orange. Proteolytic reactions are indicated by solid arrows. Ca, divalent calcium ions; PS, membrane surface-exposed phosphatidylserine; TF, tissue factor; PT, prothrombin.

Figure 2 Effects of thrombin. Arrow A: Thrombin cleaves short fibrinopeptides from the central region of fibrinogen. The newly exposed termini spontaneously associate with the terminal domains of adjacent molecules allowing formation of polymeric fibrin. Arrow B: Proteolytic cleavage of factor XIII converts it into an active transglutaminase (XIIIa) that chemically cross-links adjacent fibrin molecules, providing structural integrity to the clot. Arrow C: Thrombin cleaves the extracellular region of protease-activated receptors (PARs) on the platelet surface. This modification exposes a tethered ligand that auto-activates the PAR, leading to platelet activation. Activated platelets aggregate to form a hemostatic plug and expose phosphatidylserine (PS), providing a procoagulant surface for the coagulation cascade. Arrow D: Feedback downregulation of the coagulation cascade. Thrombin binds to thrombomodulin on the surface of endothelial cells. This association alters the substrate specificity of thrombin such that it cleaves protein C (PC) to form activated protein C (APC). In the presence of calcium and the cofactor protein S (PrS), APC promotes anticoagulation by proteolytically converting factors Va and VIIIa to their inactive forms (Vi and VIIIi).

The Role of Thrombin

Thrombin is a multifunctional enzyme that employs limited proteolysis to effect a variety of biochemical reactions at the site of vascular injury (Figure 2). Thrombin has many physiological roles, such as promoting the formation of a cross-linked fibrin clot, the activation and aggregation of platelets, and, ultimately, the attenuation of the clotting cascade.

Fibrin Polymerization

Fibrinogen is one of the more abundant proteins in the blood, circulating at a concentration of $\sim 3 \text{ mg ml}^{-1}$. The fibrinogen molecule consists of six individual polypeptide chains arranged roughly in a dumbbell shape, with the amino termini localized to a central core and the carboxy termini located at each of the two ends. The carboxy terminal end comprises binding pockets that are unoccupied in the circulating fibrinogen molecule. Thrombin converts fibrinogen to fibrin by selectively cleaving short peptides (fibrinopeptides) from the central core region, thereby exposing new amino termini that interact with the carboxy terminal binding pockets on adjacent fibrin molecules (Figure 2, arrow A). In this way, fibrin monomers associate to form thin fibrils that thicken to form an insoluble fibrin clot.

Fibrin Cross-Linking by Factor XIIIa

When fibrin is formed, it accelerates the conversion of factor XIII to XIIIa in a reaction catalyzed by thrombin in the presence of calcium ions (Figure 2, arrow B). Factor XIIIa is unique among the coagulation enzymes in that it is not a serine protease; rather, it is a transglutaminase that covalently links the side chains of lysine and glutamine residues present in the carboxy terminal regions of adjacent fibrin molecules. This cross-linking imparts structural integrity and rigidity to the clot.

Platelet Activation

Thrombin activates platelets by limited proteolysis of proteins called protease-activated receptors (PARs). PARs constitute a small subset of a much larger family of G-protein-coupled receptors (GPCRs). GPCRs are seven-pass transmembrane proteins that transduce extracellular signals via intracellular activation of heterotrimeric G-protein signaling pathways. The PARs are unique among the GPCRs in that they utilize a tethered ligand mechanism in which limited proteolysis within the extracellular region of the receptor unmasks a protein sequence that auto-activates the receptor itself (Figure 2, arrow C). In platelets, the proteolysis of PARs 1 and 4 by thrombin results in the expression of the hallmarks of platelet activation, namely, morphological change, degranulation, the expression of surface proteins required for aggregation, and the translocation of PS from the inner to the outer leaflet of the platelet membrane.

The exposure of PS has dramatic consequences for amplification of the coagulation cascade. Under normal cellular homeostasis, PS is tightly restricted to the inner leaflet of the plasma membrane and, as such, is not exposed to the general circulation. However, the exposure of PS (whether through

translocation on the platelet surface or by mechanical disruption of cells lining the vasculature) provides a surface for the recruitment of the components of the coagulation cascade, including the serine proteases and factors V and VIII. Viewed in this light, platelet activation and subsequent PS exposure provide yet another positive feedback loop for the generation of thrombin.

Attenuation of the Coagulation Cascade

The unregulated activation of the coagulation cascade would have serious consequences for an organism, including the occlusion of blood vessels and the formation of clots at locations other than the site of injury. Numerous serine protease inhibitors are present in the blood, and serve to restrict coagulation to sites of vessel injury. The most abundant among these is antithrombin, which is present at a concentration ~ 3 times that of prothrombin. Antithrombin rapidly and irreversibly inactivates thrombin, particularly in the presence of heparan sulfate, a proteoglycan present in the blood vessel wall. Antithrombin has also been shown to inhibit factors IXa, Xa, and XIa.

In an alternative mechanism for attenuating the coagulation cascade, thrombin initiates a pathway that leads to the destruction of factors Va and VIIIa. In this pathway, thrombin binds to thrombomodulin, an integral membrane protein located on the vascular endothelium (Figure 2, arrow D). As the name implies, thrombomodulin modulates the specificity of thrombin such that it generates activated protein C (APC), by limited proteolysis of protein C. APC then inactivates both factors Va and VIIIa by minor proteolysis in a reaction that requires calcium ions, anionic phospholipid, and the protein cofactor, protein S.

Structure and Function of the Blood-Clotting Proteases

Similarity to Trypsin

The proteases involved in blood coagulation are functionally and structurally related to trypsin, the prototypical serine protease of the digestive system. Like trypsin, the proteases involved in blood coagulation (thrombin, APC, and factors VIIa, IXa, Xa, and XIa) constitute a class of serine proteases that cleave their target proteins after basic (arginine and lysine) amino acid residues. However, trypsin cleaves nonspecifically after basic residues, whereas proteases of the coagulation cascade recognize and cleave only after basic residues surrounded by specific sequences within their targets. As is the case with the clotting proteases, trypsin exists in a zymogen form (trypsinogen) that is activated by limited proteolysis. Thus, while trypsin does not possess the high degree of substrate specificity of the coagulation proteases, it shares the same general mode of zymogen activation and mechanism of catalysis.

The three-dimensional representation of trypsinogen solved by X-ray crystallography reveals a two-lobed structure resembling a clamshell with a cleft running between the two individual halves (Figure 3). The primary catalytic machinery of trypsin, the so-called 'catalytic triad', consisting of histidine, aspartic acid, and serine residues, resides within this cleft. (It is the catalytic serine residue from which the serine proteases

Figure 3 Related structures of trypsinogen, trypsin, and thrombin. The structure of trypsinogen (upper left panel) reveals clamshell topology with a cleft harboring the active site. Residues His57, Asp102, and Ser195 constitute the catalytic triad (blue oval). In the inactive (zymogen) form of the enzyme, the side chain of Asp 194 does not contact the amide nitrogen (blue atom) of Ile16 (bounded by red oval). The preceding 15 residues have been omitted from the structure to provide ease of interpretation. The structure of trypsin (upper right panel) illustrates the structural change upon zymogen activation. Here, the newly formed amino terminus at Ile16 forms a salt bridge with the side chain of Asp194. The structure of thrombin (lower left panel) illustrates its overall topological similarity with that of trypsin. The light chain of thrombin is shown in green. The structure of thrombin bound to the leech anticoagulant protein hirudin (lower right panel) demonstrates the molecular basis for hirudin's anticoagulant effect. Hirudin (depicted as a blue ribbon) blocks the active site of thrombin and extends an arm around thrombin to block its fibrinogen-binding exosite.

derive their name.) Trypsinogen is catalytically inactive until it is cleaved just prior to an isoleucine residue located near the amino terminus of the molecule. This proteolytic event triggers a subtle rearrangement of the molecule, driven by the generation of an electrostatic interaction between the positively charged amino group at the new amino terminus and a negatively charged aspartic acid residue adjacent to the catalytic serine residue. The formation of this salt bridge alters the structure of trypsin and renders it catalytically active.

The structure of thrombin is remarkably similar to that of trypsin (Figure 3), as are those of the other coagulation proteases. Thrombin shares with trypsin its overall clamshell structure, its catalytic triad, and its mode of zymogen activation upon limited proteolysis. However, in addition to the trypsin-like catalytic domain (heavy chain), thrombin possesses an

additional polypeptide (the light chain) – a property shared by the other clotting proteases. In addition, thrombin possesses a secondary binding site on its surface that confers specificity for both fibrinogen and PAR1. The position of this so-called ‘fibrinogen-binding exosite’ is illustrated in the structure of thrombin complexed with the leech salivary protein hirudin, which exerts its anticoagulant effect by simultaneously blocking access to the active site and occupying the fibrinogen-binding exosite with a long arm (Figure 3).

Gla Domains

The presence of both a catalytic heavy chain and a light chain is a common feature of the activated coagulation proteases. However, in contrast to thrombin, which has a relatively short light chain, the light chains of factors VIIa, IXa, Xa, and APC are longer and are characterized by the presence of multiple modular protein domains. (The crystal structure of factor IXa illustrates this arrangement; Figure 4(a).) When viewed in the same orientation as previously depicted structures of trypsinogen, trypsin, and thrombin, the serine protease domain with its characteristic catalytic triad is clearly visible. However, this orientation obscures the light chain, which consists of an amino terminal Gla domain followed by two tandem modules that bear structural and sequence similarity to epidermal growth factor (EGF1 and EGF2). The modular structure of the factor IXa light chain is visible when the protein is rotated (Figure 4(b)).

The Gla domain derives its name from a modification of glutamate (Glu) residues that occur during the biosynthesis of factors VII, IX, and X, prothrombin, and protein C. The amino terminal 45 residues of these proteins contain between 9 and 13 Glu residues that are converted to γ -carboxyglutamate (Gla) residues in a reaction that requires vitamin K as a cofactor. Gla residues are capable of binding divalent ions, particularly calcium. The three-dimensional structure of factor IXa, determined in the absence of calcium, reveals an amino terminal Gla domain that is relatively disordered, with Gla residues projecting into solution. However, at physiological calcium levels found in the blood, the Gla residues coordinate with calcium and drive the Gla domain into its native conformation (Figure 4(c)). In this form, the Gla domain is organized around a nearly planar array of calcium ions and projects a hydrophobic ‘thumb’ into solution. It is believed that the hydrophobic thumb associates with the hydrophobic regions of membranes, while the positively charged calcium ions associate electrostatically with the negatively charged head groups of PS exposed on coagulation-promoting surfaces such as the surface of activated platelets.

Gla domains are essential for localizing factors VIIa, IXa, and Xa, and APC, as well as their zymogen forms, to PS on the surface of activated platelets located at sites of vascular injury. (Thrombin is unique in that its Gla domain is removed from the light chain during the proteolytic activation of prothrombin.) The essential role of Gla domains and the Gla residues that they bear in directing the components of the coagulation cascade to PS-containing surfaces is underscored by the anticoagulant effect of warfarin, a potent vitamin K antagonist. Warfarin inhibits the conversion of Glu residues to Gla residues, rendering the clotting factors incapable of binding to the

Figure 4 The role of Gla domains in the blood-clotting proteases. (a) Structure of factor IXa showing the serine protease domain with amino acid residues of the catalytic triad highlighted. In this view, the light chain, consisting of a Gla domain and two tandem EGF domains, is obscured. The factor IXa structure depicted was determined in the absence of calcium ions. (b) Rotation of the structure reveals the amino terminal Gla domain as well as the EGF domains. (c) Closeup of the Gla domain of calcium-free factor IXa. In the absence of calcium, the Gla domain is relatively disordered with the Gla residues projecting outward into solution. (d) The calcium-bound form of a Gla domain. The coordination of calcium ions by Gla residues within the core of the domain drives the exposure of a hydrophobic 'thumb' consisting of a phenylalanine and a leucine residue. This region of the domain contacts the hydrophobic region of membranes. The nearly planar arrangement of positively charged calcium ions may provide specificity for negatively charged phospholipids such as PS.

platelet surface. Originally employed at high doses as a rodent poison, warfarin is currently one of the most widely prescribed drugs for depressing the coagulation cascade in patients who are at risk of heart attack or stroke.

Glossary

Hybrid proteasome A 20S proteasome with a regulatory complex (RC) at one end and a proteasome activator at the other, essentially a 26S proteasome bound to a proteasome activator.

Immuno-proteasome A 20S proteasome in which each of the three active β -subunits are replaced by interferon- γ -inducible catalytic subunits.

Proteasome activators Single polypeptide chains or small protein complexes that bind 20S proteasomes and stimulate peptide hydrolysis.

Regulatory complex (RC) A particle containing six adenosine triphosphatases (ATPases) and 12 other subunits that binds the 20S proteasome to form the 26S proteasome, the eukaryotic cell's major ATP-dependent protease.

Ubiquitin A small highly conserved protein that can be covalently attached to other proteins and to itself. Chains of ubiquitin target proteins for destruction by the 26S proteasome.

Proteasomes are cylindrical, multisubunit proteases found in eukaryotes, eubacteria, and archaeobacteria. Eukaryotic proteasomes come in two sizes, the 20S proteasome and the considerably larger adenosine triphosphate (ATP)-dependent 26S proteasome formed when the 20S proteasome binds a regulatory complex (RC). The 26S proteasome is the central protease in the ubiquitin (Ub)-mediated proteolytic pathway and is essential for a vast array of cellular processes, including cell-cycle traverse, transcription control, regulation of enzyme levels, and antigen presentation. Both 20S and 26S proteasomes can associate with protein complexes that activate peptide hydrolysis and may serve to localize the enzymes within cells.

The 20S Proteasome

Structure

The 20S proteasome is a cylindrical particle consisting of 28 subunits arranged as four rings of heptamers stacked upon one another (see [Figure 1](#)). The simpler archaeobacterial enzyme is composed of just one type of α -subunit and one type of β -subunit which form the end rings and the two central rings, respectively. Proteolysis is the province of the β -subunits, and their active sites face a central chamber within the cylinder. The α -subunit rings seal off the proteolytic chamber from the external solvent making the 20S proteasome a perfect protease to have among the critical proteins that comprise nucleus and cytoplasm. Unless a native protein is forced into the proteasome interior, it will be impervious to the enzyme. Moreover, proteasome β -subunits are not catalytically active unless they are present in the holoenzyme.

Eukaryotic proteasomes maintain the overall structure of the archaeobacterial enzyme, but they exhibit a more complicated subunit composition. There are seven different α -subunits and at least seven distinct β -subunits. Although current evidence indicates that only three of its seven β -subunits are catalytically active, the eukaryotic proteasome cleaves a wider range

of peptide bonds. The archaeobacterial enzyme, with its 14 identical β -subunits, preferentially hydrolyzes peptide bonds following hydrophobic amino acids and is therefore said to have chymotrypsin-like activity. By contrast, the eukaryotic proteasome contains two copies each of trypsin-like, chymotrypsin-like, and post-glutamyl-hydrolyzing subunits. For this reason, it is capable of cleaving almost any peptide bond having difficulty only with Pro-X, Gly-X, and, to a lesser extent, with Gln-X bonds. There is a further complication in higher eukaryotes. In immune tissues, or after exposure to interferon γ , the three catalytically active β -subunits found in the proteasomes of most organs are replaced by β -subunits with differing substrate specificities. Thus, in higher vertebrates there are constitutive and immuno-proteasomes. The latter are thought to play an important role in class I antigen presentation.

Enzyme Mechanism and Proteasome Inhibitors

Whereas most proteases use serine, cysteine, or metals to cleave peptide bonds, the proteasome employs N-terminal threonines in an unusual catalytic mechanism. The N-terminal threonines, generated by self-removal of short peptide extensions from the active β -subunits during assembly of the 20S particle, act as nucleophiles during peptide hydrolysis. There are highly specific inhibitors of the proteasome. The fungal metabolite lactacystin and the bacterial product epoxomicin covalently modify the active site threonines and inhibit the enzyme. Both compounds are commercially available; other inhibitors include vinylsulfones and various peptide aldehydes that are generally less specific.

The 26S Proteasome

Whereas bacteria may possess as many as five ATP-dependent proteases, the 26S proteasome is the only ATP-dependent protease discovered so far in the nuclear and cytosolic

Figure 1 20S proteasomes. At the top are ribbon diagrams of an archaeobacterial proteasome (left) and a eukaryotic proteasome (right) as revealed by X-ray crystallography. Schematic representation of their subunit arrangements is shown below each crystal structure. Note that the archaeobacterial proteasome is assembled from 14 copies of a single α -subunit and 14 copies of the same β -subunit. By contrast, the yeast 20S proteasome consists of two copies each of seven different α - and seven different β -subunits. From Lowe J, Stock D, Jap B, et al. (1995) Crystal structure of the 20S proteasome from the archaeon *T. acidophilum* at 3.4 Å resolution. *Science* 268: 533–539; and Groll M, Ditzel L, Lowe J, et al. (1997) Structure of 20S proteasome from yeast at 2.4 Å resolution. *Nature* 386: 463–471.

compartments of eukaryotic cells. As the 20S proteasome's internal cavities are inaccessible to intact proteins, openings must be generated in the enzyme's outer surface for proteins to be degraded. A number of protein complexes have been found to bind the proteasome and stimulate peptide hydrolysis. The most important of the proteasome-associated components is the 19S RC, for it is a major part of the 26S ATP-dependent enzyme that degrades ubiquitylated proteins in eukaryotic cells (see **Figure 2**). As its name suggests, this 19S particle is roughly the same size as the 20S proteasome, except that it is a more complex protein assemblage containing 18 different subunits. Among the RC subunits are six ATPases, an isopeptidase, a subunit that recognizes polyUb chains, and a number of subunits whose functions are yet to be determined. RC subunits are arranged in two large subcomplexes, called the base and the lid. The ATPases and two other subunits comprise the base that sits directly on the end rings of the 20S proteasome; the lid is separated from the base by what appears to be a cavity. Overall, the RC looks much like a Chinese dragonhead in negatively stained electromagnetic (EM) images.

Figure 2 Schematic representation of ubiquitin (Ub) activation and adenosine triphosphate (ATP)-dependent proteolysis of conjugated substrates. Ub molecules are activated by an E1 enzyme in an ATP-dependent reaction, transferred to a cysteine residue (yellow) on an E2 or Ub carrier protein, and subsequently attached to a substrate protein (S) by an E3 or Ub ligase. Note that chains of Ub are generated on the substrate and these are recognized by the 26S proteasome depicted in the upper right at 1/20th scale.

Presumed Mechanism

The six ATPases in the 19S RC are members of the large family of AAA nucleotidases, whose members share the common property of altering the conformation or association state of proteins. In the case of the 19S RC ATPases, they are thought to act as unfoldases and translocases. Presumably, ubiquitylated proteins are captured by the RC after which the ATPases unfold the bound substrate protein and thread it through the α -ring of the 20S proteasome for its subsequent degradation in the central proteolytic chamber (see **Figure 3**). Most of the resulting peptide fragments are 5–10 residues in length, but fragments as long as 35 amino acids can be present. Furthermore, in some cases, the 26S proteasome only partially degrades the substrate protein, releasing instead functionally processed domains.

The mechanism by which the 26S proteasome recognizes ubiquitylated proteins has not been firmly established. Ub chains containing four or more monomers are preferred substrates, and one RC subunit, called S5a, has been shown to bind polyUb. However, deletion of the gene encoding this subunit in budding yeast has only a minor impact on intracellular proteolysis. Hence, there must be other subunits or additional mechanisms, by which the 26S enzyme recognizes polyUb substrates. In this regard, there are recent reports that the 26S proteasome interacts directly with Ub ligases or ligase-associated proteins that are ubiquitylated but not degraded. It should be noted that some nonubiquitylated proteins are also degraded by the 26S proteasome.

Tissue and Subcellular Distribution of Proteasomes

Proteasomes are found in all organs of higher eukaryotes, but the degree to which the composition of proteasomes and their

Figure 3 Hypothetical reaction cycle for the 26S proteasome. A polyubiquitylated substrate is delivered to the 26S proteasome, possibly by chaperones (step 1). Substrate is bound by polyUb recognition components of the regulatory complex (RC) until the end of the polypeptide chain is engaged by the adenosine triphosphatases (ATPases) (step 2). As the polypeptide chain is unfolded and pumped down the central pore of the proteasome, a signal is conveyed to the metallo-isopeptidase to remove the polyUb chain (step 3). The unfolded polypeptide is eventually degraded within the inner chamber of the proteasome (step 4) and peptide fragments exit the enzyme.

activators varies among tissues is largely unexplored territory. At the subcellular level, 26S proteasomes are present in cytosol and nucleus where they appear to be freely diffusible. They are not found in the nucleolus or within membrane-bound organelles other than the nucleus. When large amounts of misfolded proteins are synthesized by a cell, they often accumulate around the centrosome in what are called 'aggresomes'. Under these conditions, 26S proteasomes, chaperones, and proteasome activators also redistribute to the aggresomes, presumably to refold and/or degrade the misfolded polypeptides.

Physiological Importance

Deletion of yeast genes encoding 20S proteasome and 19S RC subunits is usually lethal, indicating that the 26S proteasome is required for eukaryotic cell viability. Known substrates of the 26S proteasome include transcription factors, cell-cycle regulators, protein kinases, etc. – essentially, most of the cell's important regulatory proteins. Surprisingly, even proteins secreted into the endoplasmic reticulum are returned to the cytosol for degradation by the 26S proteasome. Given the scope of its substrates, it is hardly surprising that in higher eukaryotes, the Ub–proteasome system affects a vast array of physiological processes ranging from cell-cycle traverse to circadian rhythms to learning. The Ub–proteasome system impacts a number of human neurological diseases that include Parkinson's, Huntington's, and Alzheimer's. Mutations in components of the Ub–proteasome pathway also cause various other diseases.

Proteasome Activators

In addition to the RC, there are two protein complexes, 11S regulator (REG) $\alpha\beta$ and REG γ , and a single polypeptide chain, PA200, which bind and stimulate peptide but not protein degradation by the proteasome (see Figure 4). A fourth protein, called ecm29 in yeast, associates with the proteasome. Like the RC, proteasome activators bind the ends of the 20S proteasome, and, importantly, they can form mixed or hybrid 26S proteasomes in which one end of the 20S proteasome is associated with a 19S RC and the other is bound to a proteasome activator. This latter property raises the possibility that proteasome activators serve to localize the 26S proteasome within eukaryotic cells. At present, we do not know whether activation, or targeting, or something else is the primary function of proteasome activators.

REGs or PA28s

There are three distinct subunits of the REG called α , β , and γ . REG α and REG β form hetero-heptamers found principally in the cytoplasm, whereas REG γ forms a homo-heptamer located in the nucleus. REG α and β are abundantly expressed in immune tissues, whereas REG γ is highest in brain. In addition to their different locations, the REGs differ in their activation properties. REG $\alpha\beta$ activates all three proteasome active sites; REG γ only activates the trypsin-like subunit. There is reasonably solid evidence that REG $\alpha\beta$ plays a role in class I antigen presentation, but we have no idea what REG γ does, especially since REG γ knockout mice have almost no phenotype.

The crystal structure of REG α reveals seven subunits that form a donut-shaped structure with a central aqueous channel, and the structure of an REG–proteasome complex provides important insight into the mechanism by which REG α activates the proteasome. The carboxyl tail on each REG subunit fits into a corresponding cavity on the α -ring of the proteasome, and loops on the REG subunits cause N-terminal strands on several proteasome α -subunits to reorient upward into the aqueous channel of the REG heptamer. These movements open a continuous channel from the exterior solvent to the proteasome central chamber.

PA200

A new proteasome activator, called PA200, was recently purified from bovine testis. Human PA200 is a nuclear protein of 1843 amino acids that activates all three catalytic subunits with some preference for the peptidyl–glutamyl peptide hydrolyzing (PGPH) active site. Homologs of PA200 are present in budding yeast, worms, and plants. A single chain of PA200 can bind each end of the proteasome, and, when bound, PA200 molecules look like volcanoes in negatively stained EM images. Mutation of yeast PA200 results in sensitivity to the DNA-damaging agent bleomycin, and evidence from both yeast and mammals indicates that PA200 is involved in DNA repair.

ECM29

Another proteasome-associated protein, called ecm29p, has been identified in several recent proteomic screens. It has

Figure 4 Schematic representation of the 20S proteasome assembling with various activator proteins (regulatory complex (RC), REGs, and PA200) and with the chaperone hsp90, a protein that inhibits the enzyme.

been reported that ecm29p serves to stabilize the yeast 26S proteasome, but the human homolog of ecm29p is found predominately associated with secretory and endocytic membranes, as per an unpublished observation by Gorbea and his associates, a location suggesting a role in secretion rather than 26S proteasome stability. Ecm29p clearly associates with the 26S proteasomes; whether it activates proteasomal peptide hydrolysis is unknown.

Protein Inhibitors of the Proteasome

Two proteins have been found to suppress proteolysis by the proteasome: one of these is PI31 and the other is the abundant cytosolic chaperone, Hsp90. Both may affect how the proteasome functions in class I antigen presentation. PI31 is a 30-kDa proline-rich protein that inhibits peptide hydrolysis by the 20S proteasome and can block activation by both RC and REG $\alpha\beta$. Although surveys of various cell lines show PI31 to be considerably less abundant than RC or REG $\alpha\beta$, when overexpressed, PI31 is reported to inhibit class I antigen presentation by interfering with the assembly of immuno-proteasomes. A number of studies have shown that Hsp90 can bind the 20S proteasome and inhibit its chymotrypsin-like and PGPH activities. Interestingly, inhibition by Hsp90 is observed with constitutive but not with immuno-proteasomes, a finding consistent with proposals that Hsp90 shuttles immuno-proteasome-generated peptides to the endoplasmic reticulum for class I presentation.

Summary

The 20S proteasome was discovered in 1980 and its 26S version 6 years later. Since the 1980s, a great deal of knowledge has been gained about these two enzymes and their central importance in eukaryotic cell physiology. Still, there is much more to discover, for example, the crystal structure of the 19S RC and the mechanism by which the 26S proteasome degrades its substrates; how the 26S proteasome is itself regulated; and the extent to which proteasomal components vary among tissues in higher eukaryotes.

Glossary

AAA ATPases ATPases associated with a variety of cellular activities are part of the AAA+ superfamily of ring-shaped P-loop NTPases. AAA proteins are characterized by a highly conserved module of about 240 residues, which contains several conserved motifs, such as the Walker A and B motifs. AAA proteins consists of an N-terminal non-ATPase module, considered to be the primary substrate recognition site, followed by either one or two AAA domains (D1 and D2).

DUBs Deubiquitylating enzymes perform proteolytic cleavage of ubiquitin-protein bonds. DUBs are divided into five superfamilies: (1) Jab1/Mov34/MPN (JAMM) motif containing metalloproteases (e.g., Rpn11); (2) ubiquitin-specific processing proteases (USP/UBP, e.g., Ubp6); (3) ubiquitin C-terminal hydrolyases (UCH, e.g., UCH37); (4) ovarian tumor (OTU); and (5) Machado–Joseph disease (MJD).

Ntn hydrolases N-terminal nucleophile hydrolases are enzymes with a conserved fold and a single-residue

N-terminal catalytic residue, threonine, serine, or cysteine, which mediates the nucleophilic attack on the substrate.

19S regulatory particle 19S regulatory particles bind to both ends of the 20S core particle. They regulate substrate access to the 20S core particle, for example, based on polyubiquitylation of substrates.

20S core particle The 20S core particle is situated in the center of the 26S proteasome and harbors the proteolytically active Ntn hydrolases in its core. The cylinder-shaped complex is assembled of four stacked rings, the seven-membered alpha and beta rings, both present in two copies.

Ubiquitin The highly conserved and ubiquitous, eukaryotic protein of 76 amino acids can be linked to the ϵ -amino group of a lysine residue in a protein via its C-terminal carboxyl group (ubiquitylation). Ubiquitin monomers can form polyubiquitin chains by binding to one of the seven lysines in ubiquitin, most frequently K-48.

Introduction

The 26S proteasome is an abundant complex in eukaryotes, primarily located in the nucleus, the cytoplasm, and to a lesser extent at the endoplasmic reticulum (ER) membrane. It is composed of at least 33 different subunits and is composed of two modules: a highly conserved 20S core particle (CP) containing a central catalytic cavity and one or two 19S regulatory particles (RPs). The 26S proteasome is the most downstream element of the ubiquitin proteasome pathway (UPP). In this pathway, a cascade of three enzymes, E1 ubiquitin-activating enzyme, E2 ubiquitin-conjugating enzyme, and E3 ubiquitin ligase performs attachment of a polyubiquitin tag to the substrate, which then serves as the degradation signal for the 26S proteasome. The UPP is the major route used by eukaryotic cells for the disposal of misfolded or damaged proteins and for controlling the lifespan of proteins. As a consequence, it regulates a plethora of fundamental cellular processes, such as protein quality control, DNA repair, or signal transduction. Due to its involvement in many intracellular pathways, for example, tumor suppression by p53, the 26S proteasome has emerged as a significant drug target.

To achieve substrate-specific degradation, the 26S proteasome is highly regulated. The intricate means of regulation are reflected in a complex molecular architecture where one or two copies of asymmetric 19S RPs bind to the end(s) of the barrel-shaped CP. In this article, we summarize current knowledge on the structure of the 26S proteasome and its regulation mechanisms to perform its cellular functions.

The 20S Proteasome

20S proteasomes are present in all domains of life, that is, archaea, bacteria, and eukaryotes. Whereas the 20S proteasome is conserved and essential in all archaea and eukaryotes sequenced to date, it is only found in few bacteria, mostly actinomycetes where it is not essential. In most bacteria, ClpP, which is evolutionary more distantly related to the proteasome, has an analogous function to the 20S proteasome.

Molecular Architecture

The 20S proteasomes share a highly conserved quaternary structure for species: two types of subunits, α and β , each constitute heptameric rings and collectively form a barrel-shaped complex, arranging in an $\alpha/\beta/\beta/\alpha$ -ring fashion (Figure 1). The holocomplex measures 15 nm in length and 11 nm in diameter. A channel traverses the particle from end to end and widens into three internal cavities, each ~ 5 nm in diameter. The complexity of each of the rings ranges from homo-heptameric (e.g., in the archaeon *Thermoplasma acidophilum*) to hetero-heptameric in all eukaryotes. When composed of homo-heptameric rings, the proteasome displays a sevenfold rotational symmetry (C_7) along the cylinder axis and C_2 symmetry orthogonal to the symmetry axis, whereas the eukaryotic proteasome preserves the C_2 symmetry. According to their location within the α and β rings, subunits are sequentially numbered $\alpha 1/\beta 1$ through $\alpha 7/\beta 7$. The structure-based nomenclature differs from the classification of subunits prior to

Figure 1 Structure of the 20S proteasome. (a) Surface view of crystal structure of the *Saccharomyces* CP (blue: α -subunits, green: β -subunits). (b) The same structure as in (a) seen from the top. (c) The same structure as in (a) displayed as a cartoon view. The 2 $\times$ 3 active sites are marked in red. (d) Fold of the *Thermoplasma acidophilum* 20S proteasome α -subunit (cyan: α -helix, blue: β -sheets). The N-terminal helix H0 that blocks the active site is shown in red. (e) Fold of the *Thermoplasma* 20S proteasome β -subunit. The N-terminal, catalytically active Thr residue is shown in red. Moreover, Glu17 and Lys33 (light green) are involved in the catalytic mechanism and Ser129, Asp166, and Ser169 (dark green) maintain conformational stability of Thr1.

structure determination, for example, the $\alpha 1$ subunit is referred to as ‘alpha type-6 proteasome subunit’ in databases, such as Uniprot.

Both types of subunits, α and β , are members of the N-terminal nucleophile (Ntn) hydrolase superfamily. The proteasome subunits are well conserved: the different subunits have at least 50% similarity, while there is only $\sim 30\%$ similarity between the seven subunits within the different subunit types in same species, and even less among the α - and β -subunits. Ntn hydrolases consist of two central antiparallel β -sheets, which are flanked on either side by α -helices and open at one end to form the active-site cleft (Figures 1(d) and 1(e)). The α -subunits possess an N-terminal extension of the Ntn core structure, filling the active-site cleft, which renders α -subunits proteolytically inactive (Figure 1(d)).

In the assembled proteasome, the inner cavity or nanocompartment formed by the two β -rings harbors the active sites (Figure 1(c)). Thus, access to the active sites is prohibited by the inactive α -rings forming a pore entrance to the catalytic chamber. This regulatory principle is also referred to as ‘self-compartmentalization’. ClpP has a simpler molecular architecture than the 20S proteasome: it consists only of the two β -rings and the shielding α -subunits are absent.

Active Site

A characteristic feature of Ntn hydrolases is a single-residue N-terminal active site (Thr/Ser/Cys). In eukaryotes, only three of the seven different subunits contain the catalytic threonine

residue and display proteolytic activity ($\beta 1$, $\beta 2$, and $\beta 5$), whereas subunits $\beta 3$, $\beta 4$, $\beta 6$, and $\beta 7$ lack one or more of the critical residues and are inactive (Figure 1(c)). The threonine residue acts as both proton acceptor and donor during hydrolysis: it donates a proton to its own α -amino group and attacks the carbonyl carbon of the substrate. After cleavage the α -amino group donates the proton to the nitrogen of the scissile peptide. Proton transfer is possibly mediated by a water cluster centered in the vicinity of the N-terminus. There is no consensus of residues in the vicinity of the active site among the Ntn hydrolases. Nevertheless, several residues, all highly conserved and in close proximity to Thr1, are critical for activity of the 20S proteasome, as consistently shown by site-directed mutagenesis with archaeal, bacterial, yeast, and mammalian proteasomes (Figure 1(e)). Interestingly, the different active sites of the CP subunits display different catalytic activity: $\beta 5$ has a chymotrypsin-like active site (preferential cutting after hydrophobic residues), $\beta 2$ displays trypsin-like degradation (basic residues), and $\beta 1$ is caspase like (acidic residues).

As is the case with all known Ntn hydrolases and many other proteases, proteasomal β -subunits are synthesized as an N-terminally extended, catalytically inactive precursor to prevent premature proteolytic activity. For the formation of the active sites, the so-called propeptides must be removed posttranslationally.

Immunoproteasome and Thymoproteasome

One notable feature of the CP is the tissue-specific replacement of proteolytic subunits, resulting in the so-called immunoproteasome and thymoproteasome, which generate different sets of peptides. Interferon gamma (IF γ) induces expression of the orthologs $\beta 1i$, $\beta 2i$, and $\beta 5i$, which are then part of the immunoproteasome. It contributes to the efficient production of peptide epitopes, which are then displayed at the cell surface by the major histability complex class I to cytotoxic T lymphocytes. In Thymus, $\beta 5i$ can be exchanged by a further ortholog, $\beta 5t$, which then gives rise to the thymoproteasome.

20S Proteasome Assembly

The assembly pathway of the 20S proteasome seems to vary for different species. Prokaryotic 20S proteasomal subunits can assemble autonomously into mature form. In *Rhodococcus*, α - and β -subunits form heterodimers prior to assembling to a $\alpha_{14}\beta_{14}$ half-proteasome. By contrast, *Thermoplasma* α -subunits form heptameric rings, which may then serve as a template for the assembly of the β -ring, also resulting in a half-proteasome. The propeptide serves as an intramolecular chaperone during the assembly process: the crystal structure of the *Rhodococcus* half-proteasome indicates that the pro-peptides link the β -subunits to two neighboring α -subunits, thus increasing the affinity of the β -subunits to the α -ring by increasing the area of intersubunit contacts.

On the other hand, the eukaryotic CP requires a set of chaperones for its assembly because of the higher complexity of its subunit composition: seven different α subunits and seven different β subunits are placed in a defined arrangement. Four distinct assembly chaperones (yeast: Pba1/human homolog: PAC1, Pba2/PAC2, Pba3/PAC3, and Pba4/PAC4) and Ump1

are required for the formation of CP. The Pbas form heteromeric dimers, Pba1–Pba2 and Pba3–Pba4, which bind specific α -subunits and promote assembly of the α -rings. For the assembly of β -subunits, the α -ring serves as a scaffold, on which β subunits assemble sequentially to form a half-proteasome aided by Ump1: Ump1 likely binds to the center of the assembled α -ring, where it coordinates the processing of β -subunits, assembly of the β -ring, and dimerization of half-proteasomes. Moreover, dimerization is intramolecularly chaperoned by the C-terminal tail of the $\beta 7$ subunit. After completed CP assembly, the mature CP degrades the propeptide, Ump1, and PAC1–PAC2.

CP Gate

The N-terminal tails of the α -subunits block access to the inner proteolytic compartment of the CP, even to small peptides and unfolded proteins. Therefore, the CP behaves, with respect to folded proteins, as a latent protease, which is dependent on regulatory complexes or activators that open the gate to the CP for its catalytic activity. Most common are ATP-dependent activators: the eukaryotic 19S RP contains six AAA–ATPase subunits that assemble to a hetero-hexameric ring. In archaea, the proteasome activating nucleotidase (PAN), a homo-hexameric AAA–ATPase complex, attaches to the α -ring and induces gate

opening. Likewise the homo-hexameric AAA–ATPase ARC activates the 20S proteasome in bacteria (AAA ATPase forming ring-shaped complex, ARC). These ATPase proteins possess a hydrophobic HbYX motif at their C-terminus, which binds to the hydrophobic pockets of the α -ring and induces gate opening.

In eukaryotes, two further RPs exist in addition to the 19S RP that open the gate to the CP in an ATP-independent manner: the heptameric complex PA28/11S regulates access to the immunoproteasome, and the resulting holocomplex generates the peptides presented by the major histocompatibility class (MHC) I complex. In addition, Blm10/PA200 binds to the CP in a similar way as PA28/11S, but its function is not resolved to date.

The 26S Proteasome

The 19S Regulatory Particle and Its Subcomplexes

The 19S RP is a multi-protein complex of approximately 900 kDa. It consists of 19 different canonical subunits: six regulatory particle AAA ATPases (Rpt1–6), and 13 regulatory particle non-ATPases (Rpn1–Rpn15); the proteins Rpn4 and Rpn14 were erroneously notated as integral subunits, but later turned out to be a proteasomal transcription factor and an assembly chaperone, respectively (Figure 2). Moreover, numerous

Figure 2 Structure of the 26S proteasome. (a) Cryo-EM map of the *Drosophila melanogaster* 26S proteasome resolved to 20 Å resolution. Three different views, each rotated by 120° around the vertical axis, are shown. (b) Atomic models of the CP (blue) and the AAA–ATPases (red) fitted into the map. (c) 2x magnified view of the 20S proteasome in complex with the AAA–ATPases. The pseudo sevenfold rotational symmetry axis of the CP and the pseudo threefold axis of the AAA–ATPase hexamer deviate substantially: the center of the AAA–ATPase hexamer is shifted by approximately 30 Å with respect to the CP axis and the AAA–ATPase axis is tilted by approximately 10°. (d) Canonical 26S proteasome subunits: subunits of CP (blue), base (dark red: ATPases, light red: PC-repeat containing subunits), and lid (dark green: PCI-module containing subunits, light green: MPN domain containing subunits, cyan: Rpn15) are ordered as suggested by protein–protein interactions. (e) Approximate locations of the different steps involved in substrate degradation.

proteasome interacting proteins (PIPs) interact transiently with the 26S proteasome. Among the widely studied PIPs are the deubiquitylating enzymes (DUBs), Ubp6 and UCH37 (in most eukaryotes, but no homolog in yeast), and the ubiquitin receptors, Rad23, Dsk2, and Ddi2. The 19S RP easily dissociates into a base complex comprising the AAA-ATPases Rpt1–6, Rpn1, Rpn2 and Rpn13, and often Rpn10, and a lid subcomplex containing the remaining non-ATPase subunits.

Base

The AAA-ATPases are in the heart of the RP. The AAA-ATPases assemble to a hetero-hexameric ring in the topology Rpt1/Rpt2/Rpt6/Rpt3/Rpt4/Rpt5. Structural studies of the archaeal homolog of Rpt subunits, PAN, provided implications for Rpt structure. The ATPase domains of the Rpt subunits form a ring that directly binds the α -subunits of the CP (Figures 2(b) and 2(c)). The N-terminal coiled coils and the succeeding oligosaccharide binding (OB) domains assemble to a smaller ring (N-ring), which is placed concentrically on top of the ATPase-ring, that is, distal to the CP. The ATPase-ring of Rpt subunits is stabilized by binding of the two largest RP subunits, Rpn1 and Rpn2 (~1000 residues), suggesting both function as scaffolding proteins. Both proteins, Rpn1 and Rpn2, consist to a large extent of small bihelical repeats, proteasome cyclosome (PC) repeats, which possibly wrap around the AAA-ATPase hexamer. Rpn13 and Rpn10 are known as Ub receptors, which bind to Rpn2 and Rpn1, respectively. In addition to the canonical subunits, two non-integral DUBs, UCH37 and Usp14/Ubp6, are often found substoichiometrically in 26S proteasome preparations. Ubp6 binds to Rpn1 and UCH37 binds to the C-terminal domain of Rpn13. *Saccharomyces cerevisiae* Rpn13 lacks the UCH37 binding domain and does not possess a UCH37 homolog.

Lid

The lid complex comprises proteins of two families: Rpn3, Rpn5, Rpn6, Rpn7, Rpn9, and Rpn12 contain a characteristic module, which can be found in subunits of the proteasome, COP9 complex, and eIF3 (proteasome COP9 eIF3 (PCI) module). Rpn8 and Rpn11 share an Mpr1 and Pad1 in the N-terminus (MPN) domain, which is also found in COP9 and eIF3. Among these proteins, only the function of Rpn11 is well understood: Rpn11 is a DUB and responsible for ubiquitin removal from substrates to enable ubiquitin recycling. Since the deubiquitylating activity of Rpn11 is ATP-dependent, Rpn11 is only active in the assembled RP. The MPN domain of Rpn8, which is unable to bind Zn ions, is catalytically inactive, whereas Rpn11 shows DUB activity. Interestingly, Rpn11 has a further function: the C-terminus is essential for the maintenance of tubular mitochondrial morphology. On the other hand, the function of the PCI module containing proteins is unknown. Nevertheless, the nucleic acid interacting winged helix motif, which is part of the PCI module, may hint on a role in DNA repair, possibly in conjunction with the ~70 residue peptide Rpn15.

Assembly of 19S RP

The base and lid are assembled independently and these two complexes sequentially assemble to the 19S RP. Similar to the eukaryotic CP, the assembly of the base is mediated by four

chaperones: in yeast, Rpn14, Nas2, Nas6, and Hsm3 mediate base assembly (human homologs: Rpn14, p27, Gankyrin, and S5b). All these chaperones bind to specific ATPase subunits, resulting in the formation of three intermediate precursors, which form the base complex together with Rpn1, Rpn2, and Rpn13. These chaperones are dissociated from the proteasome during the 19S RP maturation.

Compared to the base, the mechanism of the lid assembly is less characterized. Yeast genetic studies indicate that Rpn5, Rpn6, Rpn8, Rpn9, and Rpn11 forms a core module, followed by the integration of another module consisting of Rpn3, Rpn7, and Rpn15. Association of Rpn12 completes the lid complex. The complexity of the subunit composition suggests involvement of not yet identified chaperones.

Regulatory Mechanism of the 19S RP

The mechanism of the 19S RP involves (1) recognition of polyubiquitylated substrates, (2) trimming ubiquitin chains, (3) opening the gate to the CP, (4) unfolding substrates, and (5) actively translocating them to the CP in an ATP-dependent manner. These different steps are cooperatively coupled and even the precise sequence of events is not entirely resolved.

Substrate recognition

Recognition of ubiquitylated substrates requires Ub receptors. Several ubiquitin receptors of the proteasome are identified: two of these receptors, Rpn10 and Rpn13, are canonical subunits of proteasome, whereas other known Ub receptors are categorized as PIPs: Rad23 (human homolog: hHR23), Dsk2 (Kar1), and Ddi1.

Rpn10 binds ubiquitin via its C-terminal ubiquitin interaction motif (UIM), which adopts an α -helical conformation. Rpn13 binds ubiquitin through a pleckstrin homology (PH) domain: in contrast to UIMs, ubiquitin binds to loop regions rather than secondary structural elements of the PH domain. The weakly associated shuttling Ub receptors Dsk2, Rad23, and Ddi1 contain an ubiquitin-like domain (Ubl) and an ubiquitin-associated domain (UBA) to recruit ubiquitylated substrates to the proteasome. These Ub receptors bind to ubiquitylated substrates via their UBA domain and bind to the proteasomal subunits, Rpn1, Rpn10, and Rpn13, through their Ubl domain. The interplay between these Ub receptors is not completely understood.

Deubiquitylation

Ubiquitin chains conjugated to substrates can be trimmed by DUBs before the substrate is translocated into the CP. Deubiquitylation ensures Ub recycling, but may also downregulate degradation by shortening polyubiquitin chains below the length initiating degradation. The lid subunit Rpn11 exhibits its deubiquitylating activity when coupled with ATPase subunits, suggesting that Rpn11 cleaves ubiquitin chains from the substrate immediately prior to translocation (Figure 2(e)). Two other associated DUBs, the Ub C-terminal hydrolases (UCHs), Ubp6 (human homolog: Usp14) and Uch37, act further upstream in the UPP. The UCHs may downregulate degradation by trimming of Ub chains, but they are also required for degradation of some substrates.

Gate opening

In archaea, the C-terminal residues of PAN were shown to induce opening of the CP gate. It was shown that gate opening requires three C-terminal residues: a hydrophobic residue, a tyrosine, and a residue of any type (HbYX). However, in eukaryotes not all Rpt subunits containing this C-terminal HbYX motif are able to open the CP gate: Rpt2 and Rpt5 are the only eukaryotic AAA subunits, of which the C-termini were shown to open the CP gate. Crystallographic and cryo-EM studies indicate that the HbYX motif binds to a hydrophobic pocket of the CP α -ring.

Translocation and unfolding

Translocation through the pore of the AAA-ATPase ring is coupled to the unfolding process. The AAA-ATPase N-ring was shown to exhibit chaperone function, i.e., it unfolds substrates (reverse chaperone activity). The C-terminal domains of the AAA-ATPases form the canonical AAA-ATPase ring with a very narrow channel, where a conserved aromatic-hydrophobic (Ar- ϕ) loop is located. The ATP-driven movement of the Ar- ϕ loop could pull down substrate proteins by trapping hydrophobic residues. Thus, the power stroke of the proteasomal ATPase is generated by ATP hydrolysis in a single subunit, reminiscent of the bacterial ATP-dependent protease system HslU/HslV.

26S Proteasome Regulation in the Cell

UPP in the Cell

The UPP is responsible for degradation of proteins that reside in the cytosol and the nucleus, but also membrane and secretory proteins, which are degraded by a specialized branch of the UPP, that is, ER associated degradation (ERAD), as well as some mitochondrial proteins. The UPP functions not only as a disposal machinery for misfolded proteins and for proteins damaged by stress or aging, but also as a regulator to control the lifespan of many short-lived proteins. Importantly, the 26S proteasome does not degrade all substrates completely, but it can also perform limited proteolytic processing to activate certain transcription factors, such as human NF κ B and NF κ B2. In addition to its function in ubiquitin-dependent proteolysis, the 26S proteasome was also found to degrade several non-ubiquitylated substrates, for example, ornithine decarboxylase (ODC), c-Jun, I κ B α , and p21^{Cip1}.

UPP is pivotal for cellular homeostasis because it regulates the abundance of most cellular proteins (proteomics studies indicate >75% of the entire proteome) directly or indirectly. Many PIPs beyond those discussed above are involved in proteasomal regulation in a cell, which are still far from being comprehensively elucidated; proteomics studies suggest that more than 400 proteins directly interact with the proteasome.

Proteasome and Chaperones

Molecular chaperones and the 26S proteasome seem to interact physically and cooperate in cellular protein quality control. For example, CHIP, a co-chaperone of Hsp70 and Hsp90, has E3 ubiquitin-ligase activity and mediates degradation of certain substrate proteins by the 26S proteasome. Bag-1, another Hsp70-interacting protein, was also shown to stimulate

substrate ubiquitylation and to bind directly to the 26S proteasome via its UBL domain. Thus, proteins that resist Hsp70 mediated folding may be directly tagged and degraded by recruited 26S proteasomes. The chaperone Hsp90 was shown to be required for assembling 26S proteasomes and maintaining them assembled, which may in turn regulate proteasomal activity.

Proteasome and E3 Ligases

Very little is known about the molecular mechanisms of substrate shuttling from the E3 ubiquitin ligase, where the final step of ubiquitylation takes place, to the 26S proteasome. Free diffusion of ubiquitylated substrates to the 26S proteasomes would be consistent with the rather high-binding constants observed *in vitro*. However, misfolded substrates may need to be disposed more rapidly to prevent aggregations. Indeed, E3 ligase complexes, such as Ufd4, APC, Hul5, and Ltn1 were shown to interact physically with the proteasome, indicating spatial coordination of polyubiquitylation and degradation for the respective substrates.

Degradation from Organelles

The ER does not possess its own protease(s): instead it relies on the cytosolic 26S proteasome through ERAD, which is a sub-branch of the UPP. Erroneous secretory proteins and membrane proteins are recognized and transported to the cytosol where they are ubiquitylated by membrane-associated E3 ligases. Key for subsequent degradation of almost all known substrates is the AAA-ATPase Cdc48 (human homolog: p97). In complex with its cofactors Ufd2 and Npl4, Cdc48 presumably actively escorts substrates to the 26S proteasome in an ATP-dependent manner. In ERAD, the entire mechanism of substrate recognition, translocation to the cytosol, ubiquitination and translocation to the 26S proteasome seems to be spatially and temporally highly coordinated. Since Cdc48 is also involved in the degradation of many cytosolic substrates, cytosolic degradation of many substrates might be highly coordinated as well. Moreover, proteasomal degradation of substrates from mitochondria may function analogous to ERAD, as indicated by the involvement of membrane-associated AAA-ATPases.

Summary

As the endpoint of the UPP, the 26S proteasome is involved in a plethora of intercellular pathways. In concert, the ubiquitylation machinery, Ub receptors, deubiquitylating enzymes, and translocases ensure substrate-specific regulated degradation. Structural and functional studies of the 26S proteasome revealed some details of how this giant machinery functions. However, these studies raise many further questions about 26S proteasome. How is the ubiquitylated substrate transferred into the ATPase ring? It is also puzzling how deubiquitylating enzymes remove the polyubiquitin chain with proper timing prior to protein translocation. Structure determination of the 26S proteasome will provide clues on the sequence of intermolecular events during protein degradation. Structural and biochemical studies of the 26S proteasome together with its transient interaction

partners will undoubtedly be the next challenge after obtaining a draft of the static architecture of the 26S proteasome to resolve the complex regulation of proteasomal degradation.

Glossary

Agonist Compound that stimulates a cellular receptor to give a biological response.

Antagonist Compound that binds to a cellular receptor which prevents a biological response from occurring.

Antibody Protein produced by specialized B cells after stimulation by an antigen (foreign substance), which acts specifically against an antigen in an immune response.

Glycosylation sequence A three amino acid sequence where the first amino acid is asparagine, the second

is any amino acid except proline, and the third is serine or threonine.

Proteinase Enzyme which selectively catalyzes the hydrolysis of peptide bonds.

Proteinase-activated receptor (PAR) A G-protein-coupled receptor that is activated upon cleavage of the N-terminal domain by a proteinase.

Proteinase-activated receptor activating peptide (PAR-AP) Synthetic peptide that causes activation of a PAR.

Proteinase-activated receptors (PARs) are members of a novel family of seven-transmembrane G-protein-coupled receptors (GPCRs) that were first discovered in the early 1990s. To date, four members of this family (named PAR₁, PAR₂, PAR₃, and PAR₄ in order of their discovery) have been identified and their expression has been described in various organs and across several species. PARs are unique among GPCRs in having a mechanism of activation that involves enzymatic cleavage of the receptor N-terminal domain to reveal a self-activating ligand. Thus, PAR cleavage reveals a new receptor N-terminus, often described as the 'tethered ligand', which binds to another site of the receptor to initiate signaling (Figure 1(a)). Additionally, synthetic peptides (PAR-activating peptides; PAR-APs), with sequences derived from the tethered ligand, can act as soluble ligands for the PARs (Figure 1(b)). Tethered ligand or PAR-AP interaction with the receptor leads to G-protein coupling and initiation of a complex signaling cascade, resulting in various physiological or patho-physiological responses.

Structure

Proteinase-activating receptors are comprised of about 400 amino acids (Table 1) with a sequence homology of approximately 30% between the PARs. A key structural element for the PARs, the tethered ligand, is revealed upon enzymatic cleavage at an arginine or lysine residue in the receptor N-terminus (Table 1). Much evidence has supported a key role for extracellular loop 2 of PAR₁ and PAR₂ in the activation of PARs by PAR-APs. In PAR₁, a sequence of about 10 amino acids in the N-terminal extracellular domain (residues 83–93 in human PAR₁) is also involved in signaling either by the tethered ligand or by the PAR-AP. For activation by proteinases, however, the importance of extracellular loop 2 is less clearly understood. All four PARs possess a number of potential N-linked glycosylation sequences on their extracellular domains. The human genes encoding PAR₁, PAR₂, and PAR₃ are all located on chromosome 5q13, while PAR₄ is located on chromosome 19p12.

All of the PAR genes have similar overall structures, including a single intron upstream of the tethered-ligand coding sequence.

PAR Activating and Inactivating Proteinases

Thrombin, a key coagulation cascade serine proteinase, was the first proteinase shown to activate PARs (Figure 1(a)). In fact, PAR₁ was originally described as the thrombin receptor. It is now known that PAR₁, PAR₃, and PAR₄ are all targeted by thrombin. Thrombin, however, does not activate PAR₂. The most common activator of PAR₂ is trypsin, an enzyme that can also activate PAR₄.

Proteinases can also interact with PAR receptors to cleave the receptor downstream of the activation cleavage site (Figure 1(d)) resulting in a disarming of the receptor to activation by activating proteinases. For example, the neutrophil enzymes elastase, proteinase 3, and cathepsin G cleave PAR₁ on platelets and endothelial cells downstream of the thrombin cleavage site, making the cells refractory to further activation by thrombin.

Other serine proteinases that have been shown to target PARs to activate or inactivate the receptors include plasmin, granzyme A, factors VIIa/X/Xa/TF, mast cell tryptase, tissue kallikreins (hK14, hK5, and hK6), MMP-1, and dust mite proteinases (Der p3 and Der p9).

Agonist Peptides

Peptides (PAR-APs) with sequences derived from those of the tethered ligands can be used in place of proteinases to selectively activate PARs *in vitro* or *in vivo* (Figure 1(b)). Unlike thrombin and trypsin, which can act on multiple PARs, PAR-APs selective for PAR₁, PAR₂, and PAR₄ have been developed. The sequences of the most selective PAR-APs for these three receptors, as designated by the one-letter codes for each amino acid, are TFLLR-NH₂ (PAR₁), SLIGRL-NH₂ (PAR₂), and

Figure 1 Mechanisms of activation and inactivation of PARs. (a) The functional PARs cloned to date contain within their receptor N terminus a serine protease cleavage/activation site that, once cleaved by a serine protease, results in the unmasking of a cryptic tethered-ligand sequence. The revealed tethered-ligand sequence is believed to bind to and subsequently activate the receptor. The example provided (a) is for human PAR₁ activation by thrombin. (b) PARs may be activated independently of proteolytic unmasking of the tethered-ligand sequence by small synthetic peptides (PAR-APs) corresponding to the first five or six amino acids of the tethered-ligand sequence. Activation by the receptor-selective PAR₁AP, TFLLR-NH₂, is shown. (c) Intermolecular activation of PAR₁ or PAR₂ may occur following PAR₁ activation, whereby the unmasked tethered-ligand of a PAR₁ receptor activates an uncleaved neighboring PAR₂ or PAR₁ receptor. (d) Inactivation of PARs may occur by proteinases cleaving the receptor C-terminal to the tethered-ligand sequence, thus amputating the tethered ligand from the receptor body. These amputated receptors can no longer be activated by proteinases but are still responsive to exogenously applied PAR-APs. Note: a putative cysteine palmitoylation site in the C-terminal tail (present in all PARs except human PAR₄) may result in a fourth intracellular loop (not shown) that could play a role in receptor signaling. Reproduced, with permission, from Hollenberg MD and

AYPGKF-NH₂ (PAR₄), respectively (Table 1). The peptide SFLLRN-NH₂, which is identical to the proteinase revealed tethered-ligand sequence of human PAR₁, activates both PAR₁ and PAR₂. Although SLIGRL is the tethered-ligand sequence of PAR₂ in both the rat and mouse but not the human, the peptide SLIGRL-NH₂ is a more potent agonist for human PAR₂ than the human tethered-ligand-derived peptide SLIGKV-NH₂. Similarly, AYPGKF-NH₂ is 10 times more potent as a human PAR₄ agonist than GYPGQV-NH₂ or GYPGKF-NH₂, the sequences represented by the tethered ligands of the human and mouse receptors, respectively. Specific agonist peptides for PAR₃ have not been described, although a peptide with the sequence corresponding to the proteolytically revealed sequence of PAR₃ can activate PAR₁ and PAR₂.

Turning the Signal Off: Desensitization, Internalization, and Resensitization

As the tethered ligand, once exposed, cannot diffuse away from the receptor, as can agonists for traditional GPCRs, the PARs require special mechanisms to silence the signal. Two mechanisms are involved: (1) a rapid desensitization of the signal, in keeping with other GPCRs that are rapidly desensitized; and (2) receptor internalization, via mechanisms involving phosphorylation of the receptor C-tail, recruitment of β -arrestins, and targeting to clathrin-coated pits for degradation. Once activated by the tethered ligand, PARs signal to cells primarily via their interactions with a variety of G proteins (G_q, G_i, and G_{12/13}) that act as transducers of the signal. The arrestins play a key role in regulating the G-protein-signaling process. In addition, via G-protein-independent mechanisms that also involve arrestin interactions, PARs (especially PAR₂) can be internalized on a signaling scaffold. By this arrestin-dependent process, PAR₂ can signal via G-protein-independent, beta-arrestin-dependent pathways. Thus, the PARs can signal via versatile mechanisms, and the arrestins play important roles in their desensitization, internalization, and G-protein-independent signaling processes.

Once cleaved and internalized, the activated/desensitized PARs, even if they return to the cell surface, can no longer be proteinase activated. Thus, it is essential that the cleaved/activated receptors be replenished at the cell surface with intact receptors to resensitize the cells for proteinase activation. For the PARs, there are intracellular reservoirs of preformed receptors, that when called upon by cell signaling, can translocate to the cell surface, thereby replenishing a cell's store of surface-accessible PARs. The mechanisms that regulate this interesting cycle in the life of the PARs are an area of considerable interest.

Receptor Dimerization and Intermolecular Activation of PARs

In addition to the ability of proteinases and agonist peptides to activate an individual PAR directly, one PAR can be activated via a neighboring PAR in the cell membrane. For example,

Table 1 Summary of human protease-activated receptors

	PAR ₁	PAR ₂	PAR ₃	PAR ₄
Amino acid composition	425	397	374	385
Cleavage site for receptors	LDPR ⁴¹ ↓SFLLR	SKGR ³⁶ ↓SLIGKV	LPIK ³⁸ ↓TFRGAP	PAPR ⁴⁷ ↓GYPGQV
Proteinase activators	Thrombin	Trypsin, tryptase	Thrombin	Thrombin
Selective peptide agonists	TFLLR-NH ₂	SLIGRL-NH ₂	None known	AYPGKF-NH ₂

it has been demonstrated that the proteolytically revealed tethered ligand of PAR₁ can, in turn, activate PAR₂ (Figure 1(c)). Thus, theoretically, PAR₂ can generate a response to thrombin without being directly activated by the enzyme. Further, by acting as a docking site for thrombin, PAR₁ and PAR₃ can potentially facilitate thrombin's ability to activate PAR₄. In this manner, the PARs are acting as coreceptors, the one for the other. To date, although able to act as a coreceptor for PAR₄, PAR₃ has not been found to generate an intracellular signal on its own. Recent evidence has also pointed to the ability of PARs to dimerize. Use of resonance energy-transfer techniques in live cells have revealed that PAR₁ can dimerize with both PAR₃ and PAR₄, while indirect evidence exists for PAR₁ dimerization with PAR₂, as detailed above.

Antagonists

For understanding the physiological effects of the PARs fully, and for targeting the pathology of thrombin-mediated cardiovascular disorders, selective antagonists that inhibit activation

of PARs (by both proteinases such as thrombin and by activating peptides) are of great value. Thus, considerable work has been done to develop PAR-selective antagonists. Activation of PAR₁, by either thrombin or a PAR₁-AP, is inhibited by compounds 1 and 2 (Figure 2). More advanced PAR₁-antagonist compounds are currently in clinical development for the treatment of atherosclerosis, ischemia, myocardial infarction, and cerebrovascular accident (ClinicalTrials.gov Identifier: NCT00526474). PAR₂ inhibitors have been very challenging to develop. A PAR₁-related peptide, FSLLRY, was found to block trypsin, but not PAR₂-activating peptide triggering of PAR₂, but the potency of the compound was too low to be considered as a useful antagonist for studies done *in vivo*.

The peptide, LIGK, was found to inhibit both trypsin and peptide-dependent activation of PAR₂ and was, therefore, used as a basis to synthesize a peptidomimetic PAR₂ antagonist, ENMD-1068 (N-1-3-methylbutyryl-N-4-6-aminohexanoyl-piperazine) (Figure 1). This compound was used *in vivo* to diminish joint swelling in an animal model of arthritis, which is known to involve PAR₂ activation. However, the potency of ENMD-1068 is also too low to be considered

for further use *in vivo*. More recently, two other peptidomimetic PAR₂ antagonists, K12940{(N-[1-(2,6-dichlorophenyl)methyl]-3-(1-pyrrolidinylmethyl)-1Hindol5yl)aminocarbonyl}-glycyl-L-L-phenylalanine-N-benzylamide and K-14585 {(N-[1-(2,6-dichlorophenyl)methyl]-3-(1-pyrrolidinylmethyl)-1Hindol5-yl)aminocarbonyl}-glycyl-L-L-phenylalanine-N-benzylamide, have been shown to inhibit PAR₂-dependent responses *in vitro* and *in vivo*. But, again, the potency of these compounds is insufficient for their further use as a therapeutic agent *in vivo*. Thus, although the development of PAR₁ antagonists for potential clinical use has been successful, much more work must be done to develop clinically useful PAR₂ antagonists.

The development of PAR₄ antagonists is just beginning. Its activation in rodent platelets can be inhibited by compound 3 (tc-YPGKF-NH₂; Figure 2), but this peptide PAR₄ antagonist, that blocks rodent PAR₄ may not block PAR₄ from other species. A small-molecule PAR₄ antagonist, YD3 [1-benzyl-3-(ethoxycarbonylphenyl)-indazole], has been found to block PAR₄ activation of human platelets, but has been found to have off-target activity (e.g., blocking the rat platelet adenosine diphosphate receptor) in rodent platelets and may, therefore, not be of general utility to evaluate PAR₄ function in systems other than the human platelet. A novel approach to developing PAR₄ antagonists has targeted the intracellular receptor domains that interact with G proteins to trigger signaling. Cell-penetrating peptides (N-palmitoylated, to promote internalization), termed 'pepdudins', have been designed to disrupt PAR-G-protein interactions. Effective PAR₄ inhibition has been demonstrated with the use of the pepducin P4pal-i1, an N-palmitoyl cell-penetrating peptide modeled on the third intracellular loop of PAR₄. Pepducins-targeting PAR₁ have also been described, but no work has yet been done to see if targeting PAR₃ might block PAR activity.

PAR-targeted antibodies may also prove of use as systemic receptor antagonists. As an alternative to small-molecule PAR antagonists, antibodies that restrict the access of proteinases to the activation/cleavage site have proved of value. Thus, a PAR₂-targeted antibody that blocks trypsin activation of this receptor has proved of value to attenuate joint swelling in an *in vivo* model of arthritis.

Distribution

PARs have been detected in a variety of tissues by northern blot analysis. The brain, lung, heart, stomach, colon, kidney, small intestine, liver, pancreas, testes, prostate, uterus, placenta, trachea, thymus, lymph node, skeletal muscle, and adrenal gland have all been shown to have at least one of the PARs. Table 2 summarizes the tissues and cells in which each PAR is found. It is important to note, however, that cellular expression is not necessarily conserved across species. For example, human platelets express PAR₁ and PAR₄, while mouse platelets express PAR₃ and PAR₄.

Detection Methods

Expression of PARs in tissue and cells is characterized with standard methods of detection including reverse-transcriptase/polymerase-chain reaction (RT-PCR), northern blot analysis,

and immunohistochemical analysis. A number of specific antibodies targeting the PARs have been developed and are available commercially. For PAR₁, antibodies targeting different epitopes within the receptor include ATAP-2, WEDE-15, and SPAN-12, as well as a number of other commercially available antibodies. Similarly, PAR₂ antibodies targeting different sites within the receptor have been described and include B5, SLAW-A, and Sam-11, as well as others. A number of polyclonal antibodies targeting PAR₃ and PAR₄ are also commercially available.

Successful ligand-binding assays have been described for PAR₁ using the PAR-AP-derived radioligand [3H]haTRAP (alanine-parafluorophenylalanine-arginine-cyclohexylalanine-homoarginine-[3H] phenylalanineamide). For PAR₂, two different tritiated ligand probes, 2-furoyl-LIGRL[N(3H)propionyl]-O-NH₂ and 2-furoyl-[H³]LIGRL-NH₂, have been developed. The ornithine-containing PAR₂ ligand-binding probe has also been derivatized with a fluorescent tag (2-furoyl-LIGRL[N-(Alexa Fluor 594)-O]-NH₂) for use in binding studies and for visualizing the receptor on cells and tissue.

Bioassays

Measurement of Calcium Signaling

All of PARs 1, 2, and 4 can couple to Gq and mobilize calcium from intracellular stores through activation of phospholipase C, which then converts phosphatidyl inositol 4,5-bisphosphate to inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol. The IP₃ causes calcium to be released from the endoplasmic reticulum, thus increasing the intracellular calcium levels. Measurement of this increase in intracellular calcium concentration provides a good measure of receptor expression and function. Calcium mobilization can be measured in cells preincubated with a fluorescent cell-permeable calcium-sensitive dye (Fluo-4, Fluo-3, Fura-2, etc.). Activation of PARs results in an elevation in cytoplasmic calcium levels, which can be measured using a fluorescent spectrophotometer, plate reader, or microscope. To confirm whether or not an unknown agonist or proteinase activates a certain PAR, cross-desensitization experiments can be performed. For example, PAR-expressing cells can be treated first with a PAR-specific agonist (maximum dose) to desensitize the specific PAR receptor population in those cells. This pretreatment is then followed by addition of the unknown agonist that of itself can cause an increase in intracellular calcium. If a calcium response is no longer observed for the unknown agonist, but still present for a PAR-unrelated compound (e.g., lysophosphatidic acid), it can be concluded that the unknown agonist indeed does act via that particular PAR receptor. By contrast, if the PAR-desensitization protocol does not prevent the unknown agonist from triggering a calcium response, it can be concluded that it stimulates the cell through another PAR-unrelated mechanism.

Tissue Bioassays (Contraction or Relaxation)

To better understand how the activation of PARs leads to a biological response, blood vessel and intestinal smooth muscle strips may be treated with PAR-APs to monitor the contractile or relaxant activities. The relaxation of rat aorta via the endothelium-dependent nitric oxide-mediated pathway

Table 2 Localization and potential roles of the human proteinase-activated receptors

	PAR ₁	PAR ₂	PAR ₃	PAR ₄
Tissue distribution ^a (northern blot analysis)	Brain, lung, heart, stomach, colon, kidney, testis	Prostate, small intestine, colon, liver, kidney, pancreas, trachea	Heart, kidney, pancreas, thymus, small intestine, stomach, lymph node, trachea	Lung, pancreas, thyroid, testis, small intestine, placenta, skeletal muscle, lymph node, adrenal gland, prostate, uterus, colon
Cellular expression	Platelets, endothelium, vascular smooth muscle, leukocytes, GI tract epithelium, fibroblasts, neurons, mast cells	Endothelium, leukocytes, GI tract epithelium and lung, airway and vascular smooth muscle, neurons, mast cells, keratinocytes, lung fibroblasts, renal tubular cells	Airway smooth muscle, platelets	Platelets, megakaryocytes
Known physiological role	Platelet activation			Platelet activation
Potential physiological roles	Pro-inflammatory, embryonic development, regulation of vascular tone	Pro-inflammatory, mediator of nociception, airway protection, regulation of vascular tone	Cofactor for PAR ₄	Platelet activation

GI, gastrointestinal.

^aInformation for PAR₂, PAR₃, and PAR₄ is provided for human tissues; for PAR₁, distribution is recorded in rat tissues, for which more extensive data are available than in human tissues. can be measured. Similarly, contraction of the rat gastric longitudinal muscle or the endothelium-free aorta tissue can be assessed. For the bioassay experiment, a tissue is suspended between force-transducer calipers under a resting tension in an organ bath. Changes in tension are detected by measuring the displacement transducer signal coupled to an amplifier and a data acquisition system. Known compounds that cause a relaxant or contractile response, other than the PAR-activating agonists, are first added to the organ bath to verify the responsiveness of the tissue. For example, acetylcholine is known to relax precontracted aortic rings via an endothelium-dependent process, and potassium chloride is known to cause a large contractile response in smooth muscle from the stomach or blood vessels by acting directly on the tissue to cause depolarization, and thus contraction. The response to the PAR-APs added to the organ bath is then monitored and compared to the responses generated by KCl (contraction) or acetylcholine (relaxation). As in the calcium-signaling assay, cross-desensitization experiments can be performed to assess the potential contribution of each PAR to the biological response.

Platelet Aggregation

Platelets are known to express PARs 1, 3, and 4, but not PAR₂. Activation of PARs on platelets causes aggregation. Using a light-transmission aggregometer, platelet aggregation can be monitored by measuring the turbidity of a suspension of platelets. Simply by adding agonists to a suspension of platelets, aggregation can be quantified either as a percentage increase in light transmission relative to that of the initial platelet suspension, or as a percentage of the maximal aggregation, versus time. This assay is commonly used to determine whether or not a compound is an agonist or an antagonist of PAR₁ and PAR₄. For example, if an antagonist is added before a specific PAR-AP, the aggregation of the platelets will be diminished.

In addition to monitoring the aggregation response, calcium signaling can also be measured in platelets in response to PAR activation as described in the section Measurement of Calcium Signaling.

Physiological Roles of PARs

PAR₁ plays an aggregatory and secretory role in human platelets and a role as a regulator of endothelial cell function in blood vessels. PAR₁ has also been shown to have an important role in the process of narrowing the arteries after vascular injury. PAR₂ has been suggested to be involved in the cardiovascular, pulmonary, and gastrointestinal systems, as well as having an important role in the settings of inflammation and pain sensation. As the only role of PAR₃ shown to date is that it functions as a cofactor for thrombin-mediated activation of PAR₄, its physiological role is the same as for PAR₄. PAR₄, like PAR₁, has been shown to be responsible for the activation of platelets in humans and other species, and is also thought to be involved in interactions between the endothelium and leukocytes. Further, PAR₄ is implicated as a receptor involved in nociception and analgesia. There are many other physiological roles of PARs that have yet to be discovered.

Glossary

Methylesterase Enzyme responsible for demethylating the target protein by hydrolysis of the methyl ester.

Methyltransferase Enzyme that transfers a methyl group from the universal methyl donor *S*-adenosylmethionine, SAM, to a carboxyl group in a target protein.

Introduction

The methylation and demethylation reactions are catalyzed by two types of enzymes: methyltransferase (MTase) and methylesterase (MEase). The MTase transfers methyl groups from the universal methyl donor *S*-adenosylmethionine (SAM), to a carboxyl group in a target protein. This converts a negatively charged carboxylate anion on the protein surface into a neutral methyl ester with concomitant formation of *S*-adenosylhomocysteine (SAH). The methyl group is subsequently removed by an MEase that catalyzes the hydrolysis of the methyl ester to restore the carboxylate anion on the target protein, with the concomitant production of methanol:

MTase : SAM + protein → SAH + methylated protein

MEase : Methylated protein + H₂ → methanol + protein

The central role of carboxyl methylation in sensory receptor function was first evidenced by the discovery that membrane receptor proteins are methylated and demethylated during bacterial chemotaxis. The involvement of methylation in sensory regulation was extended to vertebrate systems by the finding that RAS-related and heterotrimeric G proteins were subject to carboxyl methylation and demethylation. Finally, an exhaustive search for additional systems of carboxyl methylation revealed a second major regulatory locus in eukaryotic cells that involves methylation and demethylation of phosphoprotein phosphatase 2A (PP2A), the major phosphoprotein phosphatase in the brain.

To understand how carboxyl methylation works in order to regulate cellular responses to extracellular signals, it is informative to consider the role of another type of protein modification chemistry, the phosphorylation, and dephosphorylation of protein side chains. As with carboxyl methylation, protein phosphorylation is controlled by two types of converter enzymes. A kinase catalyzes the transfer of a phosphoryl group from the universal phosphodonor, adenosine triphosphate (ATP), to an acceptor residue at the surface of a target protein with concomitant formation of adenosine diphosphate (ADP); and a phosphoprotein phosphatase catalyzes the hydrolysis of the protein phosphoester with concomitant production of inorganic phosphate. Phosphorylation generally acts as a switch to control the activity of a target protein. The first example of this regulatory mechanism was obtained through studies of the regulation of glucose metabolism in muscle and liver. There, it

is shown that the release of glucose from glycogen in response to epinephrine involves the activation of a specific kinase that turns on glycogen phosphorylase by transferring a phosphoryl group from ATP to a serine hydroxyl side chain in the enzyme. This modification is later reversed by a phosphoprotein phosphatase to turn off glycogen phosphorylase under resting conditions, when glucose needs to be stored. Subsequent research has shown that regulation by phosphorylation and dephosphorylation is a ubiquitous mechanism. A typical vertebrate genome encodes upward of a thousand different protein kinases whose activities are controlled by different regulatory signals, and it has been estimated that a quarter of the proteins in a typical vertebrate cell are subject to regulation by phosphorylation and dephosphorylation.

One might suppose that carboxyl methylation and demethylation would provide the same type of switching mechanism as phosphorylation and dephosphorylation; however, this is not the case. Whereas phosphorylation is quite common, carboxyl methylation is rare and present at only approximately 2% of the level of phosphorylation. There appear to be only three regulatory protein MTase/MEase enzyme systems: one in prokaryotes that controls chemotaxis receptors and two in eukaryotes that regulate G protein and PP2A. Moreover, in these instances, carboxyl methylation does not function as an on/off switch, but serves instead to modulate the output of a regulatory network of kinase/phosphatase switches to optimize the response to a given stimulatory input.

Carboxyl Methylation in Bacterial Chemotaxis

Virtually all motile prokaryotes use the same basic mechanism to control their motor activities in response to attractant and repellent stimuli. Generally, each cell has a signal transduction apparatus composed of a cluster of thousands of α -helical hair-like fibers that traverse the cytoplasmic membrane (**Figure 1**). The portion of each fiber located at the outside surface of the membrane acts as a sensory receptor, interacting with specific attractant and repellent stimuli in the extracellular medium. The portion of the fibrous array inside the cell controls the activity of an associated protein kinase that catalyzes the transfer of a phosphoryl group from ATP to a small protein in the cytoplasm that subsequently interacts with the motor apparatus to produce a chemotaxis response. Although the

Figure 1 Model of the chemotaxis receptor fibers. Transmembrane methylatable receptors are employed as sensors in bacterial chemotaxis.

cytoplasmic domains of receptor fibers and their associated kinase/phosphatase signaling enzymes are highly conserved, the extracellular sensing domains are variable, depending on the particular stimuli with which they interact. The number of different sensory receptor fibers encoded in a given genome ranges from just a few, for example, five in the case of *Escherichia coli*, to several dozen, for example, 46 in *Vibrio cholerae*.

Stimulus–response coupling through the chemotaxis phosphorelay signaling apparatus is modulated by carboxyl methylation. Sequences within the cytoplasmic portions of each fiber between the membrane spanning domain and the kinase regulatory domain contain a series of at least four glutamate residues that are subject to methylation and demethylation by specific MTase and MEase enzymes. The degree of methylation of the glutamyl carboxylate side chains controls the link between stimulus binding to the extracellular sensory portions of the fibrous array and the intracellular kinase. In most bacteria, lower levels of methylation act to increase the cell's sensitivity to attractant stimulation. The level of methylation is controlled by several parameters including the availability of SAM and feedback from the kinase, as well as by conformational changes in the fibers induced by stimulus interactions with the extracellular sensory receptor domains. Since changes in methylation occur at a much slower rate than changes in kinase activity, methylation provides an adaptive mechanism, whereby the sensory apparatus adjusts the phosphorylation response to fit a given background stimulus intensity. The result is analogous to light–dark adaptation in vertebrate visual systems, where sensitivity is shifted in response to background light intensity.

Carboxyl Methylation of Eukaryotic Signal Transduction Proteins

Responses of eukaryotic cells to extracellular signals are generally mediated by sensory receptor proteins that traverse the cytoplasmic membrane. Portions of these proteins at the cell surface interact with hormones and other stimuli. These interactions cause structural changes in portions of the proteins that extend into the cytoplasm, and these changes act in turn to cause associated G proteins to exchange bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP). The G

Figure 2 Sequence of processing events involved in isoprenylcysteine carboxyl methylation. The methylated molecules are soluble GTPases in the cytosol, which are targeted to the membranes by a series of posttranslational C-terminal modifications that include prenylation, C-terminal proteolytic cleavage, and carboxyl methylation.

proteins in their GTP-bound state are activated to produce second messengers such as cyclic adenosine monophosphate (cAMP) that activate protein kinases, which regulate key enzymatic activities by phosphorylating serine and threonine side chains. The phosphoryl groups are subsequently removed through the action of phosphoprotein phosphatases, such as PP2A. These types of signal transduction pathways are modulated by the carboxyl methylation and demethylation of alpha carboxyl groups at the C termini of the G proteins and PP2A. Thus, although the chemistry is somewhat different, carboxyl methylation modulates receptor-mediated responses in eukaryotes just as in bacterial cells.

Carboxyl Methylation of Ras-Related and Heterotrimeric G Proteins

A majority of carboxyl-methylated proteins in eukaryotic cells are Ras-related and are heterotrimeric G proteins. These signal transduction proteins are targeted to membranes, where they relay information from sensory receptors. Membrane targeting depends on a series of posttranslational C-terminal modifications that include prenylation, proteolytic cleavage, and carboxyl methylation (Figure 2). The initial event, prenylation, depends on a characteristic C-terminal tetrapeptide, termed a 'CaaX motif', consisting of a cysteine, C, followed by two aliphatic amino acids, aa, and a final amino acid that is variable, X. The prenyl group is either a C-15, farnesyl or a C-20, geranylgeranyl, polyisoprenoid, depending primarily on the nature of the C-terminal X residue. In either case, prenylation causes the G protein to become associated with endoplasmic reticulum (ER) membranes, where a membrane-associated protease catalyzes the cleavage of the aaX sequence, leaving a prenylcysteine alpha carboxyl group at the C terminus. This is the site of methylation by a specific MTase and of demethylation by one or more MEase activities.

G-protein methylation is catalyzed by an integral membrane protein that is localized in the ER. This MTase, termed 'isoprenylcysteine methyltransferase (ICMT)', has a broad specificity for prenylcysteine alpha carboxyl groups. First identified in *Saccharomyces cerevisiae* (STE14p), ICMTs have

since been shown to be conserved from yeast to humans. ICMTs are not protein specific – they even catalyze the methylation of small-molecule amino-acid analogs, such as *N*-acetyl-*S*-farnesylcysteine or *N*-acetyl-*S*-geranylgeranyl cysteine. Functional characterizations of ICMT interactions with methyl-accepting substrates have been performed primarily with these analogs, which have recently been shown to possess anti-inflammatory properties by altering G-protein signaling. The rate of methylation is controlled at several levels: G-protein activation leads to increases in methylation, and elevated levels of SAH lead to product inhibition. Methylation is not required for receptor-mediated G-protein signaling *per se*, but rather acts to modulate stimulus–response coupling. The physiological importance of isoprenylcysteine carboxyl methylation has been demonstrated with ICMT^{−/−} knockout mice, which die at embryonic day 11.5, designating *Icmt* as an essential gene for mouse embryonic development. Furthermore, use of *Icmt*-deficient and conditional *Icmt* mutant fibroblasts inhibited both Ras- and Raf-induced oncogenic transformation and led to mislocalization of Ras proteins.

Carboxyl Methylation of Phosphoprotein Phosphatase 2A

PP2A is generally isolated as a heterotrimeric complex consisting of three subunits: A, B, and C. The 65-kDa, A subunit serves as a scaffold for the association of the 36-kDa catalytic C subunit and regulatory B subunits. Although AC dimers are abundant in tissue, ABC trimers of the PP2A enzyme are prevalent *in vivo*. Although only two isoforms of the A and C subunits have been reported so far in humans, there are several different unrelated families of B subunits. These are, in large part, responsible for the specificity of PP2A toward the thousands of different potential phosphoprotein substrates in

vertebrate tissues. It has been estimated that PP2A is responsible for roughly half of the total phosphoprotein phosphatase activity. PP2A is one of the most abundant enzymes in brain, where, among other functions, it plays a critical role in the regulation of axonal microtubule assembly.

The PP2A catalytic subunit has a highly conserved C-terminal extension, the last six residues, TPDYFL, being identical in all PP2As. The alpha carboxyl group of the C-terminal leucine residue is the site of methylation and demethylation (Figure 3). Methylation is essential for the assembly of PP2A holoenzymes. The discovery of the PP2A methylation system led to the purification and characterization of specific enzymes responsible for PP2A methylation and demethylation.

The PP2A MTase was initially purified from bovine brain as a soluble 38-kDa monomer. The enzyme appears to be completely specific for the methylation of PP2A AC dimers. PP2A methyl esters are hydrolyzed by the action of a specific MEase with similar specificity. The PP2A MEase has been purified from bovine brain as a soluble 46-kDa monomer. The MTase and MEase are highly conserved in species ranging from yeast to human, and the structures regulating this reversible methylation reaction have been solved (Figure 3).

Methylation appears to function primarily to regulate the assembly of PP2A heterotrimeric holoenzymes (Figure 3). Differential methylation of PP2A has been observed during cell cycle progression, suggesting that methylation might be altering the subcellular localization of PP2A. Selective microtubule-associated PP2A is differentially regulated during the cell cycle, implying that PP2A is regulated by methylation. PP2A methylation seems to play an important role in growth control. Mutant yeasts that completely lack PP2A MTase activity are resistant to rapamycin, and are sensitive to antibiotics, such as nacotazol, that inhibit microtubule function. It has been proposed that, in humans, product inhibition of PP2A by SAH in brain may help explain

Figure 3 Carboxyl methylation regulates PP2A by controlling the association of regulatory B subunits. The PPMT enzyme binds to unmethylated AC and catalyzes the transfer of a methyl group from SAM to the C subunit. The methylated AC dimer is then able to bind regulatory B subunits. Methylated AC dimers are subject to demethylation by a specific methylesterase, PME. The Pymol software was used to generate the figure with the following PDB ID (PP2A: 3DW8, PPMT: 1RJD, PPME: 3C5V).

why elevated homocysteine levels are a risk factor for Alzheimer's disease since homocysteine can condense with adenosine to generate SAH. Furthermore, low levels of AC-dimer methylation in Alzheimer's disease correlate well with deficiencies in PP2A activity, leading to hyperphosphorylated tau, and the formation of a neurofibrillary tangle.

Glossary

Curation The process of evaluating, validating, and annotating experimental or derived data.

Hidden Markov model A statistical model in which a system is assumed to be a Markov process (with fixed conditional transition probabilities between system states) but with unobserved state.

Ontology In information science, a formal representation of the knowledge within a domain by

an agreed hierarchical set of concepts forming a controlled vocabulary, with the definitions relating those concepts forming nonrecursive, nested subsets.

Proteomics The study or analysis of the set of proteins expressed by an organism, their relationship to the genes coding for them, and to the physiological and pathological processes affecting their structure and function.

Primary Sequence Data

Humorists have observed that as we mature professionally, we learn more and more within an increasingly specialized area of knowledge until ultimately we know almost everything there is to know about nothing at all. The knowledge being acquired about proteins is suffering a similar fate. The rising flood of protein sequence translations coming from genome sequencing results necessarily means that a smaller and smaller fraction of those sequences can actually be studied experimentally as proteins. The computer is now one of the most powerful tools we have for studying proteins. From the computer-automated sequencing of polynucleotides, through the assembly of polynucleotide reads into genomes, through the interpretation of the genes into transcripts and translations, to the comparison of protein sequences and their contexts in the effort to discern their meaning, every step is done with computers. The biological databases play a central role in this computer-driven flow of biology. The biological databases, made possible by computer technology, provide access to the primary sources of biological information, the primary sequences. Although the first bioinformatics resource was published as a book, *The Atlas of Protein Sequence and Structure* in 1974, and most of the various bioinformatics databases produced CDROMs at one time, the access and distribution provided by bioinformatics resources today is entirely through the Internet, either by web browsers, by file transfer (ftp) of selected database segments or entries, or by server-produced query responses in computer-readable format.

Genomic Sequence and Context Resources

Genome sequences are today the starting point for comprehending biological knowledge. Now that a large number of whole genomes are available for comparison studies, it is not just the polynucleotide sequences, but also their contexts and interrelationships that database providers must attempt to

capture and present. This is currently the largest field in bioinformatics. The international collaboration taking the central role in collecting and presenting polynucleotide sequences from single genes to whole genomes consists of the National Center for Biotechnology Information (NCBI) producing GenBank, the European Bioinformatics Institute (EBI) of the European Molecular Biology Laboratory producing the Nucleotide Archive (ENA, formerly EMBL-Bank), and the Center for Information Biology and DNA Data Bank of Japan producing the DDBJ. All of the polynucleotide sequences deposited with each of these collaborators are shared and redistributed by all of them, but each in their own legacy format or set of formats.

The contextual relationship of genes is important in understanding how they are expressed and function, but most especially in how they evolve. In predicting the function of a particular protein, it is important to know whether the genes being compared are considered to be orthologous (derived from genes with ostensibly the same function in different species) or paralogous (derived from genes that may have acquired different functions after gene duplication). The availability of whole genomes provides a more direct means of assessing whether homologous sequences are orthologous with the same function, or paralogous with related but different functions. Assembled genomic information is available from several resources. The EBI produces Ensembl, which is focused on vertebrate genomes, and Ensembl Genomes, focused on nonvertebrate species and presently organized in five divisions, metazoa, protists, bacteria, plants, and fungi. The NCBI produces the Genome Database, and the Database of Genomic Structural Variation. Another useful resource in this area is eggNOG, a database of clustered orthologous groups with functional annotation.

Protein Primary Sequence Resources

UniProt, the universal protein resource, is a comprehensive resource for protein sequence and annotation data. It is produced by the UniProt Consortium consisting of the European

Bioinformatics Institute, the Swiss Institute of Bioinformatics (SIB), and the Protein Information Resource (PIR). The PIR produced the original *Atlas of Protein Sequence and Structure* and later the first bioinformatic database, the Protein Sequence Database. In 1986, SIB began producing Swiss-Prot, later being joined by the EBI in co-producing Swiss-Prot and TrEMBL. In 2002, the three institutes formed the UniProt Consortium to pool their resources and expertise. The primary database produced by the Consortium is the UniProt Knowledgebase (UniProtKB) produced in two divisions, the curated Swiss-Prot and the automatically annotated TrEMBL. Other databases are UniProt Reference Clusters (UniRef), the UniProt Archive, and the UniProt Metagenomic and Environmental Sequences database, a repository of unannotated metagenomic and environmental protein sequence data. The resource provides a unified web portal maintained jointly by each Consortium member. The most current listing of database formats and web access tools is published in the annual Database issue of *Nucleic Acids Research*.

The NCBI produces RefSeq, a database of nonredundant translated protein sequences. Basic local alignment search tool (BLAST) protein sequence searches are performed on the RefSeq nonredundant database of all coding sequence translations from GenBank, along with UniProt and the Protein Data Bank (PDB). The Protein Clusters database is a representative set of nearly identical RefSeq sequences that are encoded by complete prokaryotic, mitochondrial, and chloroplast genomes organized taxonomically. The Protein Clusters database is used as a basis for genome comparison at the NCBI and can be used in simplified BLAST searches. The most current descriptions of the protein sequence database resources produced by the NCBI are also published in the annual Database issue of *Nucleic Acids Research*.

Protein Modification and Secondary Structure Resources

Although most protein sequence information in the primary structure resources is derived from the translation of polynucleotide sequences, those translations tell us nothing about how those protein structures are altered by posttranslational processing, and almost all proteins are processed in some way, usually beginning with the removal of the initiator methionine. Typical protein processing includes the cleavage of signal and activation peptides, the covalent modification of amino acid side chains, of N- and C-terminals, and of the polypeptide backbone. The tight and sometimes highly specific binding of metals and metal complexes also changes the covalent structure.

There are a number of web resources for predicting certain particular types of modifications, such as phosphorylations or glycosylations, or for signal or targeting sequences. Especially notable are resources such as those developed by the Research Institute of Molecular Pathology Bioinformatics Group in Vienna, Austria, and by the Center for Biological Sequence Analysis at the Technical University of Denmark. The RESID Database of Protein Modifications is a resource providing a comprehensive collection of the chemical structure of natural protein modifications that have been reported, and includes the controlled vocabulary used to describe those modifications in the feature annotations of the UniProt Knowledgebase.

Proteomics and Protein Interaction Resources

After genome sequencing data, the largest growth in bioinformatics has been in two areas that are usually grouped together as representative of proteomics, protein interaction data and proteome mass-spectrometry data. The International Molecular Exchange (IMEx) consortium of protein interaction databases includes IntAct, DIP, MINT, MPact, MatrixDB, MPIDB, and BioGRID. Protein interaction data in the entire core IMEx databases are accessible using the Proteomics Standard Initiative (PSI) Common Query Interface. This interaction data include the interactions of proteins with other proteins and other molecules, important experimental approaches in studying protein function. Similarly, the ProteomeXchange consortium consists of the proteomics repositories, the EBI PRIDE (Proteomics Identifications Database), the NCBI Peptidome, the Institute for Systems Biology PeptideAtlas, the Proteome Commons Tranche repository and the Global Proteome Machine Organization gpmDB. The ProteomeXchange consortium aims to exchange mass spectrometry-based proteomics data and to ensure data availability in all member databases. Data derived from large-scale proteomics experiments are stored either in databases with curation guaranteeing annotation to some minimum acceptable level, or in data repositories with no curation and depositors usually required to meet standards for minimum acceptable annotation, such as the minimal information about a proteomics experiment (MIAPE).

In order to perform the mass-spectrometric identification of peptides for proteome analysis, it is necessary to construct libraries of expected peptide sequences. If the peptide library contains large numbers of sequences from sources that are not contributing to the experimental sources, then the rate of false-positive identifications becomes unacceptably high. The UniProt Consortium had produced the International Protein Index (IPI) as a source of splice form-derived peptide sequences for human and other model organisms. The UniProt Consortium is committed to providing an ongoing resource for proteome-derived peptide identifications, but plans have not been finalized for how this resource will be structured.

Three-Dimensional Protein Data Resources

The Protein Data Bank

From the early days of macromolecular atomic structure determination, researchers have publicly shared results of their data as atomic models. In the mid-1970s, this was formally organized into the PDB, a computer-based repository for macromolecular structures. Today, the PDB is split over three sites RCSB PDB (USA), PDBj (Japan), and PDBe (Europe) and coordinated under the World Wide PDB (wwPDB). It holds descriptions of the atomic models derived from data collected from X-ray crystallographic, nuclear magnetic resonance (NMR), electron microscopy, fiber diffraction, neutron diffraction, and solution scattering experiments. Data are held in two formats: as a prescribed text formatted file and as a controlled condensed format called the 'crystallographic information file (CIF)'. It also holds some other data derived from the experiment such as the structure factors from X-ray experiments. This

allows the electron density used to generate the deposited atomic model to be calculated. In addition, details of the experiment itself are cataloged. Each entry is given a unique four-character alphanumeric code. Researchers are encouraged to deposit their atomic models and experimental data by requirements from scientific journals for a deposition code prior to consideration for publication.

All three sites provide access to the deposited data in the original agreed deposition format. In addition, each provides alternative views and modes of access, including dynamic creation of personal queries and result views. Likewise, resources such as PDBSum bring together additional data resources, checking, visualization, and computation of derived features in the context of the protein structure and present this in a variety of data views.

Protein 3D Models Predicted from Sequence

In comparison to the number of protein sequences that are cataloged, there is a paucity of experimentally determined structural information. This is not only due to the sheer volume of protein sequences, combined with the time and resources required to gather structural data, but also because so many proteins are not amenable to current structure determination experiments. To overcome this, a wide range of computational methods and pipelines have been developed to predict the 3D structure from sequence. Resources exist which hold predicted models automatically generated by such prediction methods, for example, ModBase, as well as online prediction services and metasearchers that take a poll from running a number of predictions from individual resources. Developments in this field can be followed via the bi-annual Critical Assessment of Structure Prediction (CASP), a community-wide experiment that aims to assess the ability to predict protein structure.

Protein Structure Classification and Integration with Sequence Data Resources

There are almost as many approaches to protein classification as there are researchers in the field. The first project driving bioinformatics was the collection of protein sequences so they could be aligned and compared. Working with comparison tools like Fasta and BLAST, and alignment tools like Clustal and Needleman-Wunsch, it became apparent that most proteins could be viewed as consisting of modules, commonly referred to as 'domains', that persisted across broad taxonomic ranges, occasionally being tandemly repeated in the same protein, duplicated in paralogous proteins, shuffled with other domains, and reorganized in linear assemblies to form different proteins. With experience, most researchers were confident that their sequence comparison methods could recognize protein domains that were probably related by evolution down to about 30% similarity. As more protein conformations were determined during the 1980s and 1990s, it was observed that most of these sequence domains possessed conserved folds and conformations, and that they represented structural domains. These structural domains were conserved and could be recognized as conformationally similar even in sequences with as little as 20% similarity. Today, a number of protein

classification schemes using powerful detection methods are cooperating to provide insights into how evolution has shaped the structures of proteins.

Class, architecture, topology, and homologous superfamily (CATH) is a hierarchal classification scheme of protein structures. Proteins are segmented into structural domains that are assigned to homologous superfamilies (groups of domains probably related by evolution). The classification is based on four criteria, class (determined according to the secondary structure composition and packing within the structure), architecture (the overall shape of the domain structure), fold or topology (sharing the same overall shape and connectivity of secondary structures in the domain core), and homologous superfamily. Another approach is used by structural classification of proteins (SCOP), in which the hierarchal classification also reflects both structural and evolutionary relatedness. The principal levels are family (with a clear evolutionarily relationship), superfamily (low sequence identities, but whose structural and functional features suggest a common evolutionary origin), and fold (proteins sharing the same major secondary structures in the same arrangement and with the same topological connections). Pfam uses an approach designed to scale with growth in the number of new protein sequences. Seed alignments are created, many automatically, from relatively stable and consistent genetic translations. The seed alignments are used to build profile hidden Markov models (HMMs) that are used to search sequence databases for potential homologs. Those homologs that score above curated thresholds are included in the alignment for iterative refinement.

InterPro is a resource integrating the results of classification methods of 11 InterPro consortium member databases (PROSITE, Pfam, SMART, TIGRFAMs, PIRSF, SUPERFAMILY, PANTHER, Gene3D, PRINTS, HAMAP, and ProDom). The member databases use different methods based on string regular expressions, fingerprints, profiles, or HMMs to develop diagnostic signatures for protein domains and families. Together, the different signature recognition methods, coupled with statistical and biological significance tests, allow any failings in the individual methods to be recovered. A particular method for detecting sequences belonging to a certain class may miss some true examples, false negatives. Using a combination of methods increases overall sensitivity by decreasing the false-negative rate. However, this is done at the cost of increasing the false-positive rate. Taking into account the intersection of the results of the different methodologies increases the reliability of the classification and its sensitivity. The basis set of sequences for the InterPro classification methods are updated with every UniProtKB release and then used for the next round of classification of UniProtKB entries.

Protein Function Resources

Annotating and Ascribing Protein Function

Most, if not all, resources ascribe some form of annotation for the protein data they present. Annotations fall into two categories: those determined from experimental observation and those predicted using computational methods. Annotations of experimental observations are obtained either at the time of

deposition from the depositor or, more often, from extensive searching of associated literature by highly trained curators from the data resource. Emerging text-mining techniques now permit the automatic annotation using the scientific literature. Where either time to search the literature or experimental data is lacking, many data resources use computational techniques to infer functions for nonannotated entries from the manually curated entries. Most methods for automated annotation use evolutionary relationships either at the sequence level or at the structural level. Accuracy of the annotations decline as the evolutionary distances between proteins increases. Moreover, incorrect or inappropriate annotations can be easily passed on by these inference methods resulting in a phenomenon termed 'genome rot'. It is vital therefore that the provenance of the annotation be recorded and considered.

Functional Annotation Resources

The first organized attempt to classify proteins by function came when the Enzyme Commission (EC) was set up by the International Union of Biochemistry in 1955 to produce a classification and standard nomenclature for enzyme activities. The four-level numeric identifiers and standard names produced by the EC used by all bioinformatics resources were published first as books, and are now available in tables on the web with some text searching capability. In recent years, the rising flood of biochemical information has carried with it a small proportion of enzyme activity reports that has nonetheless overwhelmed the capabilities of the EC with its very limited staff to cope with the demands. Enzyme activity reports in the modern era often fail to provide many of the clear experimental results and delimitations that were expected in enzyme research before 1990, making the work of the EC more difficult. One approach to providing a bioinformatics resource for enzyme information has been the building of relational databases with web access like ENZYME Database and IntEnz with more powerful search capabilities and links to publication, chemical, and biological resources.

The appearance of the first complete genome sequences created a need for a systematic organization of biological cellular processes so that the functions of genes could be more precisely described within the limits of experimental results with varying degrees of ambiguity. Fortunately, mathematical logic, information science, and linguistic research had already produced the means of expressing ambiguity with precision – ontologies, formal representations of knowledge by a hierarchical set of concepts within a domain and the ordering relationships between those concepts. Work began on construction of the Gene Ontology (GO) in 1998 by a consortium of researchers studying the genome of three model organisms. It has three hierarchical controlled vocabulary components organized along orthogonal lines of conceptual categorization: cellular component, molecular function, and biological process. Along with the usual verbal description of what has been determined about a protein's function and role in an organism, the UniProt Knowledgebase also provides the more precise GO terms that can be associated with each protein. The GO

Consortium website provides public access to all aspects of its work from downloading of the database to participation in discussions about the definitions.

Protein Expression, Interaction, and Localization

Another important catalog of protein information relates to their expression and interaction in a cell or tissue. There are a number of experimental protocols that can characterize protein expression and interaction, including microarray analysis, yeast two hybrid, co-immunoprecipitation, and others. The results of these experiments are collated and presented in a number of resources including IntAct, BioGRID, MINT, and others. In addition to understanding interactions, other resources catalog protein-signaling pathways as well as the biochemical pathways in which protein enzymes participate. Such resources include REACTOME, KEGG, and BRENDA. To further understanding of a protein's context within a cell, other resources detail the cellular location of proteins. One of the most innovative of these has been the Human Protein Atlas, which provides a systematic exploration of the human proteome by generating fluorescently tagged antibodies against all human proteins and using them to immunohistochemically label proteins in tissues and cells, which can be observed using confocal microscopy. This is implemented in a high throughput manner using cell microarrays, allowing analysis of different cell lines and states such as those from cancer patients. The expression profiles and confocal images are presented through a web portal.

Availability and Maintenance of Resources

Changing Modes of Access to Resources

From their beginnings in the 1970s, the biological databases have depended on the availability of computer database technology. Scientific users seldom have to become involved in database programming, and probably prefer that such aspects remain invisible to them. How scientists have accessed those database resources has, however, changed most dramatically with computer technology – from books, magnetic media, and CDROMs to internet web browsing, servers, and file transfers. The biological sequences remain the primary objects of study, but as the volume of the sequence data has increased beyond comprehension, scientists have increasingly had to rely on biological database resources to provide the annotations to help them find and understand the significance of the sequences they want to study.

The ever-increasing number of protein resources (a summary of some of them described in this article is given in [Table 1](#)), and biological data resources in general, has raised issues regarding the longevity and on-going maintenance of these resources. Once a resource has been developed, it can be difficult to find funding to maintain it. The movement of the resources' developers as they follow their careers can also exacerbate the problem of maintaining a resource's presence. In addition, the expected large increase in data from the second and third generation of sequencing technologies as well as the big biology projects currently being undertaken will generate questions about how the data is to be maintained. To begin to address this, a European initiative has been started to construct

Table 1 Major protein resources

- Protein Sequence Databases
 - UniProtKB – comprehensive collection of determined and translated protein sequences with annotations that are manually curated, or automatically derived from manually curated homologous sequences (<http://www.uniprot.org/>)
 - RefSeq – integrated, non-redundant, annotated set of translated protein sequences, including genomic DNA, and transcripts (<http://www.ncbi.nlm.nih.gov/refseq/>)
 - GenBank – annotated collection of all publicly available DNA sequences (<http://www.ncbi.nlm.nih.gov/genbank/>)
 - ENA – annotated collection of all publicly available DNA sequences (<http://www.ebi.ac.uk/embl/>)
 - DDBJ – annotated collection of all publicly available DNA sequences (<http://www.ddbj.nig.ac.jp/>)
 - Entrez – multidatabase search engine (<http://www.ncbi.nlm.nih.gov/sites/gquery>)
 - Ensembl and Ensembl Genomes – comparative genome databases for vertebrates and other eukaryotic species (<http://www.ensembl.org/> and <http://www.ensemblgenomes.org/>)
 - eggNOG – database of orthologous groups of genes (<http://egglog.embl.de/>)
- Proteomic Data Resources
 - PRIDE – proteomics data resource providing a repository for protein and peptide identifications together with the evidence supporting these identifications (<http://www.ebi.ac.uk/pride/>)
 - The IMP-IMBA Bioinformatics group – portal to site predictions for GPI-anchors, N-myristoylations, prenylations, and protein kinase A phosphorylations (<http://mendel.imp.ac.at/>)
 - CBS Prediction Servers – site predictions for a number of different types of glycosylation, phosphorylation, and signal sequence processing (<http://www.cbs.dtu.dk/services/>)
 - RESID – comprehensive collection of annotations and structures for protein modifications including amino-terminal, carboxyl-terminal, and peptide chain cross-link posttranslational modifications (<http://www.ebi.ac.uk/RESID/> and <http://www.ncifcrf.gov/RESID/>)
- Protein Structure Databases
 - wwPDB – Database and tools for access PDB data (<http://www.wwpdb.org/>)
 - PDBSum – Summaries of all protein structures (<http://www.ebi.ac.uk/pdbsum/>)
 - ModBase – Database of Comparative Protein Structure Models (<http://modbase.compbio.ucsf.edu/modbase-cgi/index.cgi>)
 - LiveBench – assessment of current protein structure prediction servers (<http://meta.bioinfo.pl/livebench.pl>)
- Protein Classification
 - CATH – Hierarchical classification of protein structural relationships (<http://www.cathdb.info/>)
 - SCOP – provides a detailed and comprehensive description of the structural and evolutionary relationships between all proteins whose structure is known Structural Classifications of Proteins (<http://scop.mrc-lmb.cam.ac.uk/scop/>)
 - PFAM – Database of protein domain families represented by multiple sequence alignments and hidden Markov models (<http://pfam.sanger.ac.uk/>)
 - GENE3D – structural annotation for proteins in the main sequence databases based on CATH classification (<http://gene3d.biochem.ucl.ac.uk/Gene3D/>)
 - InterPro – integrated database of predictive protein ‘signatures’ used for the classification and automatic annotation of proteins and genomes (<http://www.ebi.ac.uk/interpro/>)
- Protein Function, Interaction and Location
 - GO – The Gene Ontology used to annotate gene and gene products (<http://www.geneontology.org/GO.database.shtml>)
 - KEGG Database – integrated database resource consisting of 16 main databases, broadly categorized into systems information, genomic information, and chemical information (<http://www.genome.jp/kegg/>)
 - ENZYME Database – a repository of information relative to the Enzymes Commission characterisation of an enzymes function using Nomenclature Committee of the International Union of Biochemistry and Molecular Biology definitions (<http://expasy.org/enzyme/>)
 - IntEnz – resource focused on enzymatic reactions and chemical nomenclature in collaboration with the ENZYME database (<http://www.ebi.ac.uk/intenz/>)
 - IntAct – proteomics data resource for curated experimental evidence of protein interactions with proteins and other molecules, and repository for submitting interaction data (<http://www.ebi.ac.uk/intact>)
 - BIOGRID – data repository compiled through curation of protein and genetic interactions from major model organism species (<http://thebiogrid.org/>)
 - MINT – database of experimentally verified protein–protein interactions (<http://mint.bio.uniroma2.it/mint/Welcome.do>)
 - REACTOME – curated pathways database encompassing many areas of human biology (<http://www.reactome.org/>)
 - BRENDA – an enzyme specific database cataloging many aspects of protein enzymes (<http://www.brenda-enzymes.info/>)
 - Human Protein Atlas – database detailing expression and localization of proteins in a large variety of normal human tissues, cancer cells, and cell lines (<http://www.proteinatlas.org/>)

The table presents some of the major protein resources as mentioned within the text and their current online location. This is by no means an exhaustive list of resources available; one web source, the Online Bioinformatics Resources Collection (OBRC) of the Health Sciences Library System, University of Pittsburgh (<http://www.hsls.pitt.edu/guides/genetics/obrc>) maintains a database containing annotations and links for more than 2600 bioinformatics databases and software tools.

and operate a sustainable infrastructure for biological information in Europe to support life science research. Its aim is to secure funding from governmental, industrial, charitable, and intergovernmental agencies to provide an infrastructure to integrate, maintain, and manage current and future European biological data resources.

Maintaining Access to Primary Publications in an Electronic Era

Another major change in how science has been done in the past 5 years is how that science is published. First, all major scientific journals are now published in on-line form. One

study of academic library journal usage found that within 3 years of the introduction of an on-line format for a journal, the on-line use could be expected to outstrip print use by a factor of ten. Academic libraries no longer have to find ever more shelf space for their print journals. In addition, with the emergence of the free-access model as a viable economic alternative for publication, the costs of journal subscriptions are not rising as fast, while the number of journals has continued to increase.

Some major scientific journal publishers have taken on the expense of converting print editions of their journals from before publishable electronic versions became available. This is an important development, and not only for the academic purposes of teaching the history of the biomolecular sciences from its inception, but also for the database annotators who now have greater in-depth access to the sources they need to provide the contexts of discovery along with the data. Especially, with the emergence of ontologies for controlled vocabulary development, having good on-line access to both current and more historic information is important for the work of database annotators.

The Role of Biocuration, Establishing, and Maintaining Protein Data Resources

Although the computer is a powerful tool for exploring protein structure, it is only a tool. The enterprise of constructing scientific databases critically depends on having curators and annotators who are both scientifically trained and skilled at conveying understanding clearly and concisely. A significant development for the work of database annotators has been the founding of the International Society for Biocuration. One of the objectives of the biocurators is to assist databases by

promoting standards for database annotation, by establishing best practices guidelines, and by adopting or improving standard operating procedures. They also want to publicize the work of biocurators for the scientific community and public funding agencies, and secure sustainable support for bioinformatic resources that are essential to research. A professional society will promote the relationship of biocurators with the communities of researchers, publishers, and database users to ensure that the databases biocurators produce meet the specific needs of each community. It will also foster the training of students in the work of biocuration.

Protein Degradation

A L Goldberg, Harvard Medical School, Boston, MA, USA

Published by Elsevier Inc.

Glossary

AAA ATPase (adenosine triphosphatases (ATPases) associated with diverse cellular activities) A distinct family of ATPases characterized by the presence of highly conserved domains in their primary sequence, hexameric structure, and protein unfolding activity.

Adenosine triphosphatase (ATPase) A type of enzyme that hydrolyzes ATP and uses the energy released to drive

biological processes such as pumping ions, unfolding proteins, and moving molecules.

Folding A process in which newly synthesized polypeptides attain their native three-dimensional structures.

Molecular chaperones Specialized proteins, many are ATPases, that prevent protein aggregation and may function to facilitate proteins attaining their native conformations; some can promote protein unfolding and solubilization of aggregated proteins.

Nearly all proteins within cells and most in the extracellular space are continually turning over, being synthesized from amino acids and, after widely divergent life spans, are broken down back to amino acids. The term 'protein degradation' refers to several intracellular processes by which proteins are broken down to their basic constituents. Protein degradation occurs in all living species, from bacteria to humans, and is mediated by the sequential action of several endo- and exopeptidases. Because cells use significant amount of energy for new protein synthesis, the continual destruction of proteins might appear highly wasteful. However, this process serves several important functions that are essential for life. (1) The degradation of intracellular proteins is a highly selective and tightly regulated process that is required for removal of many regulatory proteins (transcription factors and signal transducers) and many key rate-limiting enzymes, whose rapid degradation is essential for precise regulation of metabolic pathways and for maintaining cellular homeostasis. Unlike most regulatory mechanisms (e.g., phosphorylation and ubiquitylation), peptide bond cleavage is an irreversible process, and protein degradation therefore acts as a unidirectional biological switch. (2) The only way that cells can reduce the steady-state level of a particular protein is by proteolytic degradation, and removal of certain proteins permits cells to adapt their composition to changes in the cellular environment and new physiologic conditions. This kind of adaptation occurs in mammals; for example, in the liver during fasting when enzymes for glycogen production are degraded and enzymes required for gluconeogenesis are induced. (3) Under fasting conditions, protein breakdown, especially in skeletal muscle, also serves as a source of amino acids that provides the organism with essential precursors for gluconeogenesis, protein biosynthesis, or energy production. (4) The continuous breakdown of cell proteins functions also as an important quality-control mechanism that selectively removes abnormal misfolded proteins that may arise by mutations, postsynthetic damage (e.g., by oxygen radicals), biosynthetic errors (e.g., misincorporation of amino acids and premature termination of translation), or failures of normal folding or assembly of multimers. The frequency of such events in cells is uncertain in part because the resulting misfolded proteins are rapidly degraded. (5) In higher

vertebrates, protein degradation is also critical for the function of the immune system. The mechanisms defending against both intracellular pathogens (e.g., viruses) and ones in the extracellular space (e.g., bacteria) depend on the continual production of peptide antigens by intracellular proteolytic pathways.

In eukaryotic cells, there are two principal pathways for complete degradation of proteins: the endocytic-lysosomal and the ubiquitin-proteasome pathways. The former occurs primarily within the membrane-enclosed autophagic vacuoles, and the latter operates in the soluble cytosol and nucleus (Figure 1). These pathways involve very different enzymes and serve different functions in the cell. Additional proteolytic systems are also present in some organelles (e.g., mitochondria or chloroplasts). Bacteria and archaea do not have lysosomes or ubiquitin but, nevertheless, possess soluble and membrane-bound proteases, many of which have homologs that catalyze proteolysis in mitochondria and chloroplasts. Most extracellular proteins (such as plasma proteins) also continuously turn over, mainly by uptake and degradation inside cells. One critical feature of all these intracellular degradative systems is that they require metabolic energy, unlike the typical proteases functioning in the extracellular space. As explained below, energy-dependent targeting processes (e.g., protein ubiquitylation) help insure exquisite selectivity, and the adenosine triphosphate (ATP)-dependent proteolytic enzymes allow efficient protein degradation.

Endocytic-Lysosomal Pathway

This pathway is responsible for degradation of extracellular proteins, most membrane proteins, some organelles, and some intracellular proteins. The principal proteolytic component of this pathway where most protein degradation takes place is the lysosome (or the vacuole in yeast).

Lysosomes

Lysosomes are single membrane-bound spherical organelles in the cytoplasm. They were discovered by Christian de Duve and

Figure 1 Pathways of protein breakdown in mammalian cells. Most intracellular proteins in the cytosol, nucleus, and ER are degraded by the ubiquitin–proteasome pathway (right panel). Extracellular and autophagocytized proteins and most membrane proteins are broken down within the endocytic–lysosomal compartment (left panel). Substrates are delivered to this pathway by receptor-mediated endocytosis (1), pinocytosis (2), phagocytosis, (3), autophagy (4), and a selective process for some cytosolic proteins containing specific amino acid motifs (5). Some internalized membrane proteins are recycled back to the plasma membrane (dotted arrows). After the internalized material is enclosed in vesicles (a), the vesicle fuses with primary lysosomes (b) derived from the Golgi complex and ER to form secondary lysosomes where final degradation takes place. Degradation products are transported across the lysosomal membrane into the cytosol. Some plasma membrane proteins are broken down by the ubiquitin–proteasome pathway, and some cytosolic proteins are degraded in lysosomes (dashed arrows). Although worn-out mitochondria are cleared by autophagy, mitochondrial proteins are selectively broken down by their own ATP-dependent proteases.

co-workers in the mid-1950s and are found in all mammalian cells except red blood cells. Lysosomes are not found in higher plants, but the plant cell vacuole performs some of their degradative functions. Lysosomes play an important role in innate immunity, adaptation to stress or starvation, recycling of cytoplasmic organelles, development, cell differentiation, and some forms of programmed cell death.

Uptake of substrates

Lysosomes receive substrates for degradation by fusing with other intracellular vesicles that are formed by endocytosis (endosomes, pinosomes, and phagosomes) or autophagy. Endocytosis refers to the process of uptake of extracellular material or membrane proteins by invagination of the cell membrane, followed by formation of vesicles inside the cell in the endosomal (ESCRT, endosomal sorting complex required for transport) pathway. Before these vesicles reach the lysosomes (pH 4.5–5.0), ingested material moves from the less acidic early endosomes (pH 6.0–6.5) to the more acidic late endosomes (pH 5.0–6.0). There are three major forms of endocytosis: (1) receptor-mediated endocytosis (uptake of membrane proteins, such as cell surface receptors and their ligands), (2) pinocytosis (ingestion of extracellular liquid with its solute molecules), and (3) phagocytosis (engulfing of large particles such as bacteria or apoptotic bodies by specialized cells such as neutrophils, macrophages, or amoeba) (Figure 1). Pinocytosis and phagocytosis are not selective bulk processes, but receptor-mediated endocytosis is a highly specific, often regulated cellular process that is used, for example, by most cells to take up extracellular products (e.g., lipoproteins and transferrin) or to reduce the levels of surface receptors (downregulation) after the receptors are occupied by ligands, or to internalize antigens using antibodies on the cell surface as receptors

(e.g., in B lymphocytes). Autophagy is highly regulated, but generally a nonselective process that digests most intracellular material (Figure 1). It serves an adaptive role in response to nutritional deprivation and stress and is responsible for selective digestion of aggregated cytosolic proteins and redundant or damaged intracellular organelles, such as mitochondria and peroxisomes. In addition, some cytosolic proteins that contain specific amino acid motifs (e.g., KFERQ) are transported into lysosomes selectively through a specific energy-, chaperone-, and receptor-mediated process (termed ‘chaperone-mediated autophagy’) that is activated by nutrient deprivation (Figure 1).

Lysosomal enzymes

Lysosomes contain at least 50 different hydrolytic enzymes, which catalyze the breakdown of proteins, nucleic acids, carbohydrates, and lipids into their components. The isolation of lysosomal hydrolases in this vesicular compartment is essential for protecting against nonspecific degradation of key cell constituents. However, during necrotic cell death, lysosomes release their content, which helps destroy the cell. Release of lysosomal enzymes outside of cells causes severe inflammation and contributes to the symptoms of some diseases (e.g., gout). Most lysosomal enzymes are optimally active at an acidic pH of 4–6, and the pH within activated lysosomes is maintained in this range by a membrane adenosine triphosphatase (ATPase) that functions as a hydrogen ion pump. Most lysosomal proteases are called ‘cathepsins’, and most belong to the family of cysteine proteases. The most abundant proteases are cathepsins D and L (endopeptidases) and cathepsins B and H (exopeptidases). The acidic milieu in lysosomes not only keeps lysosomal enzymes in their most active state, but it also helps denature protein substrates, which enhances their

susceptibility to proteolytic digestion. Once the protein substrates are degraded, the products of their digestion are transported across the membrane into the cytosol, where they are further metabolized.

Additional roles of the endocytic pathway

The endocytic-lysosomal (ESCRT) pathway plays an important role in maintaining the structural integrity of the plasma membrane by continuously recycling internalized membranes and some membrane receptors back to the cell surface. In addition, in specialized antigen-presenting cells (macrophages, dendritic cells, and B cells), some 15–20 residue peptides derived from the breakdown of extracellular proteins escape complete destruction and become bound in late endosomes to specialized membrane receptors, called ‘major histocompatibility (MHC)’ class II molecules. These complexes are transported to the cell surface for presentation to a subpopulation of T lymphocytes responsible for generation of humoral immune responses against non-native proteins (e.g., ones from pathogens).

Ubiquitin-Proteasome Pathway

Most cytosolic and nuclear proteins are degraded by the ubiquitin-proteasome pathway (Figure 2). This system catalyzes the breakdown of most long-lived proteins, which comprise the bulk of proteins in cells, and of short-lived proteins that regulate a wide variety of essential cellular processes, ranging from cell-cycle progression to signal transduction and gene transcription. In addition, this pathway catalyzes the selective elimination of misfolded, or mutated proteins, which are continuously produced due to imperfections in protein biosynthesis and folding or to postsynthetic damage. A critical clue to the discovery of the nonlysosomal ubiquitin-proteasome pathway by Hershko, Ciechanover, Goldberg, and collaborators was the finding that the breakdown of intracellular proteins was ATP dependent, which was surprising because the peptide bond cleavage by proteases is thermodynamically favored and does

not require energy. Biochemical dissection of this pathway in the early 1980s revealed that it consists of two ATP-dependent processes: the conjugation of the small protein ubiquitin to proteins, which marks them for degradation, and the hydrolysis of ubiquitylated proteins by the very large proteolytic complex, the 26S proteasome (Figure 2) (S refers to Svedberg units – the velocity at which the protein sediments in an ultracentrifuge).

Ubiquitin Conjugation

Formation of polyubiquitin chains

In order to be degraded by 26S proteasomes, most intracellular proteins must be first conjugated to a chain of ubiquitin molecules. This process ensures that only selected substrates are degraded in a regulated manner and prevents the uncontrolled degradation of other cellular proteins. Ubiquitin is a 76-residue globular protein, which is present only in eukaryotic cells, and not in bacteria and archaea, where highly selective protein degradation does occur, but through ATP-dependent proteolytic enzymes that function independently of ubiquitin. Conjugation of ubiquitin to other proteins and the formation of polyubiquitin chains is mediated by the sequential action of three types of enzymes, called E1 (ubiquitin-activating enzyme), E2s (ubiquitin-conjugating enzymes), and E3s (ubiquitin-protein ligases). In this process, the E1 enzyme activates ubiquitin in an ATP-dependent reaction by forming a highly reactive thiolester linkage between the C-terminus of ubiquitin and the thiol group in the active site of the E1. The activated ubiquitin is then passed from the E1 to a sulfhydryl group on one of the cell’s approximately 30 E2s. Next, the activated ubiquitin molecules are linked to a lysine side chain (or in some cases, to the N-terminal amino group) on the substrate protein, directly from the E2 as occurs with the Ring family of ubiquitin ligases. In the case of the homologous to E6-AP carboxy terminus (HECT) family of E3s, there is a transfer of activated ubiquitin from the E2 to the E3 before transfer to the substrate. A single E2 may function with multiple E3s to

Figure 2 Ubiquitin-proteasome pathway for degradation of intracellular proteins. In eukaryotic cells, the site for degradation of most intracellular proteins is a large proteolytic particle, termed the ‘26S proteasome’. Protein substrates destined for degradation by the 26S proteasome are first polyubiquitylated in ATP-dependent manner in a series of reactions involving at least three groups of enzymes (see text for details). Polyubiquitylated substrates are rapidly hydrolyzed by the 26S proteasome and monomeric ubiquitin is recycled by the action of deubiquitinating enzymes. The energy of ATP is required for ubiquitin conjugation, binding, and unfolding of a substrate and its translocation into the inner cavities of the proteasome. Most peptides produced by proteasomes are further degraded to amino acids by endo- and exopeptidases in the cytosol and nucleus, but a small fraction of peptides escapes complete hydrolysis and are utilized for MHC class I antigen presentation. Some proteins are conjugated to only a single ubiquitin molecule. This modification does not mark proteins for degradation by proteasomes but is utilized for regulation of cellular processes, such as endocytosis and transcription.

provide specificity in a combinatorial fashion. Cells contain more than 600 distinct E3, which are the main determinants of substrate specificity and are capable of recognizing a few or multiple protein substrates that share specific degradation signals (often termed 'degrons'). E3s are soluble or membrane-bound proteins; some are monomeric enzymes containing distinct domains for binding a substrate and a specific E2 enzyme, while others are very complex oligomeric structures in which different subunits subserve different functions required for highly specific substrate recognition and efficient ubiquitylation. A polyubiquitin chain is synthesized by linking additional ubiquitin molecules to the lysine residues on the previously conjugated ubiquitin. Ubiquitin contains seven lysine residues, all of which can be involved in chain formation. Proteasomal degradation generally involves polyubiquitin chains where the ubiquitin molecules are mainly linked to lysine 48. However, ubiquitin chains in cells that are composed of K63 chains serve other regulatory roles and in the endocytic pathway target membrane proteins to lysosomes. For example, ubiquitylation of cell surface receptors (e.g., growth factor receptors) with K63 chains results in their internalization and lysosomal degradation. Once a protein is conjugated to K48 or other type of chain containing four or more ubiquitins, it is rapidly degraded by 26S proteasomes.

Mechanisms of substrate recognition

Ubiquitylation of proteins is triggered by various features of the substrates that act as signals (so-called degrons) that are recognized by the E3 and thus cause degradation of the protein. These structural features can be constitutive elements in the substrate itself (e.g., an atypical specific N-terminal amino acid residue or a short internal sequence of amino acids) or can be acquired covalent modifications. Phosphorylation of substrates is one of the frequently employed acquired signals that regulate protein ubiquitylation. In many instances, this modification leads to direct recognition of a substrate by the specific E3. However, in some cases, phosphorylation of a substrate can inhibit its ubiquitylation. Phosphorylation-dependent ubiquitylation is responsible for the degradation of I κ B during the inflammatory response and of the various cyclins that control progression through the cell cycle. Other types of posttranslational protein modifications can either prevent or stimulate ubiquitylation, including acetylation, glycosylation, or attachment of the small ubiquitin-like protein, SUMO-1. An interesting posttranslational modification that induces ubiquitylation of a substrate is the oxygen-dependent hydroxylation of a specific proline residue in the transcription factor hypoxia-inducible factor-1 (HIF1)- α , whose stabilization in hypoxic conditions plays an important role in activating the transcriptional adaptation to hypoxia. Under normoxic conditions, two prolines in HIF1- α are readily hydroxylated, leading to its recognition and ubiquitylation by a specific E3. Another mechanism for substrate recognition involves the association of the substrate with an adapter protein that is required for its recognition and ubiquitylation by the specific E3 enzyme. This strategy is particularly exploited by oncogenic strains of the human papilloma virus, which uses the cellular E3, E6AP, and the viral adapter, E6, to cause destruction of the critical host factor p53. The selective degradation of unfolded proteins in mammals involves their initial binding to specific molecular

chaperones (e.g., Hsp70), which recognizes exposed hydrophobic domains on proteins and then the chaperone-dependent E3, termed 'CHIP', ubiquitylates them. For most substrates and most E3s, the degradation signals have not yet been defined nor are the functions of most ubiquitin ligases.

Deubiquitination

Ubiquitin conjugation to cellular proteins is a reversible process and the removal of a ubiquitin moiety is catalyzed by deubiquitinating enzymes, which are cysteine proteases or metalloproteases. Three such enzymes are associated with the 26S proteasome and catalyze the disassembly of the ubiquitin chain during degradation of ubiquitin-conjugated proteins. They must play important roles in recycling monomeric ubiquitin for use in new conjugation reactions, and in preventing the accumulation of free polyubiquitin chains that could act as competitive inhibitors of the binding of ubiquitylated substrates to the proteasome. There are almost 100 deubiquitinating enzymes (often termed 'DUBs') in the human genome. These enzymes also probably serve as a proofreading system, which insures that no erroneous ubiquitylation of substrates takes place. However, there are a growing number of these DUBs that function to deubiquitinate specific substrates and to oppose the actions of specific E3s. However, mutations in certain deubiquitinating enzymes can cause neuronal degeneration, and others have been shown to contribute to the occurrence of certain cancers.

Protein Degradation

The 26S proteasome

Proteasomes are abundant evolutionarily highly conserved, large multimeric complexes found in the cytosol and nucleus of all eukaryotic cells. The 26S proteasome contains about 60 subunits, is about 2.4 MDa in size and is responsible for the degradation of ubiquitylated proteins. It consists of the 20S core proteasome and one or two 19S regulatory particles (Figure 3) and comprises 1–2% of the proteins in typical mammalian cells.

The 20S core particle

In eukaryotes, the 20S proteasome is a hollow cylinder and consists of four stacked rings, each containing seven homologous subunits. There are two identical outer α -rings and two identical inner β -rings (Figure 3). Three of the subunits in each inner β -ring contain the proteolytic active sites. The outer α -rings surround the narrow openings into the 20S particle at either end, through which substrates can enter through a gated channel into the inner proteolytic chamber. These openings are tightly regulated, and protein access is enabled through the association of α -rings with different regulatory particles. This architecture with active centers isolated within the particle clearly evolved to prevent the uncontrolled destruction of cell proteins. The six proteasomal active sites in the β -rings are confined to a central chamber within the cylinder where proteins are degraded. Each of the three active subunits has a different catalytic activity: one cleaves preferentially after basic amino acids in the protein substrate (the trypsin-like site), one after large hydrophobic residues (the chymotrypsin-like site), and one after acidic residues (the caspase-like site).

Figure 3 The 26S proteasome and its regulatory components. The 26S proteasome consists of the 20S core particle and one or two regulatory 19S particles. Different structures comprising the 26S proteasome carry out distinct functions (as detailed on the picture). In addition to 19S regulators, eukaryotic 20S proteasomes can also associate with other ring-forming complexes, such as PA28 α/β or PA28 γ , or simpler proteins (PA200 or PI31). PA28 α/β is a heptameric ring composed of α and β subunits. It promotes opening the channel enclosed by α -rings of 20S proteasomes. PA28 γ is related to α and β subunits of PA28 α/β and forms a homoheptameric complex that binds to 20S proteasomes and activates mainly the cleavages after charged residues in peptide substrates. It is predominantly found in the nucleus and, in some cells, is downregulated by interferon γ . Its biological function is still not well understood. PA200 is a recently discovered 20S proteasome-interacting protein of 200 kDa that is localized in the nucleus. The mechanism of its association with proteasomes is not well understood, but like PA28, it activates only peptide hydrolysis by proteasomes. It appears to play a role in DNA repair by recruiting proteasomes to damaged DNA. PI31 is a homodimeric protein that was discovered by its ability to inhibit peptide hydrolysis by 20S proteasomes *in vitro*. Recent *in vivo* data suggest that this protein does not affect proteasome-mediated proteolysis but rather interferes with MHC class I antigen presentation by slowing maturation of immunoproteasomes.

The proteasomes belong to a novel mechanistic class of proteases. The active site nucleophile of the proteasome is the hydroxyl group of the threonine at the amino terminus of the β -subunit. The existence of this new type of proteolytic mechanism, not utilized by other known proteases, has enabled the synthesis of highly specific proteasome inhibitors. They are now very valuable, widely used as research tools (e.g., MG132), and are also widely used (Bortezomib/Velcade) in the clinic to treat multiple myeloma and other hematologic cancers.

19S regulatory particle

The 19S particle consists of at least 18 different subunits and associates with α -rings on one or both ends of the 20S proteasome. Two functionally different substructures of this complex have been distinguished: the base and the lid (Figure 3). The base, which touches and regulates the α -rings of the 20S core particle, contains eight polypeptides including six ATPases that form a ring (Rpt1-6). Once the ubiquitin chain binds to the ubiquitin-receptor subunits (Rpn10 and Rpn13), an unfolded end of the polypeptide interacts tightly with the ATPases, and this step seems to commit the protein for degradation. These ATPases use the energy of the ATP to unfold protein substrates, open the gate in α -rings, and promote rapid translocation of the substrates into the 20S core particle for degradation. The six ATPases function in a cyclic manner and cleave two ATPs in each step causing in each step major conformational changes that drive proteasome function. For example, when a subunit binds ATP, its C-terminal residues dock into intersubunit

pockets in the 20S to cause gate-opening (like a key-in-a-lock). The base of the 19S particle also contains deubiquitinating enzymes and binding sites for ubiquitin-like domains of various shuttling factors that seem to function in bringing ubiquitylated substrates to the proteasome. One of these deubiquitinating (Usp14) has regulatory functions and when it is engaged in disassembling the ubiquitin chain, it triggers gate opening in the 20S and ATP hydrolysis to promote protein degradation. The lid contains eight non-ATPase subunits with still unknown functions.

Immunoproteasome and hybrid proteasome

In higher vertebrates, a small fraction of the peptides generated by proteasomes is not completely degraded by cytosolic peptidases to free amino acids, but instead functions in immune surveillance. They are transported into the endoplasmic reticulum (ER), where they associate with specific membrane-bound MHC class I molecules and are subsequently transported to the cell surface. The immune system is continually surveying the surface of all cells for non-native peptides presented on MHC Class I molecules that may originate from viral or mutated proteins. If cells carrying such non-native peptides are encountered, they are rapidly destroyed by cytotoxic T-lymphocytes. Proteasomes found in most of the tissues (the so-called 'constitutive proteasomes') contribute to the generation of basal levels of antigenic peptides in the absence of infection. However, during inflammation, two additional types of proteasomes appear to play a major role in enhancing MHC class I antigen presentation and are termed 'immunoproteasomes'

and 'PA28-hybrid proteasomes'. In lymphoid tissues (e.g., spleen and thymus), immunoproteasomes are present exclusively, but they are induced in other tissues during infection in response to the cytokine interferon γ . Immunoproteasomes are formed by replacement of all three catalytic β -type subunits in constitutive proteasomes with alternative proteolytically active β -subunits. The alternative immunosubunits possess qualitatively different cleavage specificities than constitutive β -subunits and appear to play a major role in increasing the supply of peptides appropriate for MHC class I antigen presentation.

Hybrid PA28-proteasomes are formed when 20S immunoproteasomes are capped on one side with the 19S particle and on the other side with an alternative protein complex, called 'PA28 α/β ' (Figure 3). Most probably, in these hybrid particles, ubiquitylated substrates initially bind to the 19S regulator, and peptide products are released at the opposite side through the PA28 α/β complex which promotes the opening of the peptide exit channel enclosed by the α -rings and also favors the generation of peptide fragments particularly suitable for MHC class I antigen presentation during inflammation.

Mechanism of protein degradation

Although the exact sequence of events in which proteins are degraded by 26S proteasomes is not fully understood, a rough outline of steps can be provided. Upon binding of the polyubiquitylated substrate to its receptors and a loose terminus of the protein to the ATPases, the substrate is unfolded in an energy-dependent manner by the mechanical actions of the 19S ATPases' conformational changes, and then the unfolded polypeptides are translocated into the 20S's inner cavity. A key event is the ATP-dependent opening of the gate in α -rings allowing translocation of the unfolded substrate into the proteasome. Successful translocation of the substrate follows disassembly of polyubiquitin chain by the three 19S deubiquitinating enzymes. Translocation can occur from its amino- or carboxyl-terminus, depending on the structure of these ends, or even by an internal polypeptide loop which can enter the axial channel to permit initial endoproteolytic cleavage. In some cases, proteasomes degrade substrates only partially, yielding biologically active protein fragments, as occurs in the generation of the p50 subunit of the transcription factor NF κ B from a larger precursor and in the processing and activation of some membrane-bound transcription factors.

Once in the central chamber of the 20S particle, the substrate is cleaved by six catalytic subunits into small peptides ranging from 2 to 25 residues in length. Unlike traditional proteases, the proteasome does not simply cleave a protein and release the two fragments; on the contrary, a protein substrate in the proteasome is generally cut multiple times until small peptides are generated. This behavior ensures that partially digested proteins do not accumulate within cells. The product release may be facilitated in some cells by PA28 α/β , as well as by hydrophobic products themselves, which can trigger gate opening in α -rings. In eukaryotic cells, the peptide products generated by proteasomes are rapidly hydrolyzed into amino acids by the sequential actions of endopeptidases and aminopeptidases. The whole process of degradation of one molecule of the protein substrate requires several hundred molecules of ATP and is completed in a matter of seconds or

minutes, depending on the size of a substrate. Generally, substrates must be first ubiquitylated in order to be degraded by proteasomes. However, 26S proteasomes can degrade certain substrates *in vivo* (e.g., ornithine decarboxylase associated with cofactor antizyme) and many polypeptides *in vitro* (e.g., denatured casein and aged calmodulin) in ubiquitin-independent manner. It still remains uncertain whether *in vivo* there are more proteins that are degraded in ubiquitin-independent manner.

ER-Associated Degradation

Newly synthesized proteins that are destined to be membrane components or to be selected are translocated into the lumen of the ER or are inserted into the ER membrane. The ER contains an abundant set of chaperones and enzymes that assist newly synthesized proteins in attaining their correct conformations and activity, but sometimes, this maturation process fails and misfolded proteins are generated. Such abnormal proteins are effectively removed so as not to aggregate and form potentially toxic inclusions. This disposal process is often called 'ER-associated degradation (ERAD)'. In it, misfolded proteins are retro-translocated from the ER back into the cytosol, and after ubiquitylation on the membrane, are degraded by 26S proteasomes. This export is necessary because the ER does not contain proteolytic enzymes necessary for protein degradation. Certain ER-associated enzymes (e.g., 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase) are continually being degraded by the ERAD pathway. A key component in extracting the ubiquitinated mutant proteins from the ER is the p97 ATPase (also called 'valosin-containing protein (VCP)', which somehow helps in the delivery of the protein to the 26S proteasomes. ERAD is also used by some viruses to downregulate MHC class I molecules in the ER (e.g., cytomegalovirus) as a means of viral evasion of the immune system. The ERAD pathway is particularly important in several human diseases, such as cystic fibrosis or certain forms of α 1-antitrypsin deficiency in which the mutant proteins are rapidly degraded and therefore unable to function (Table 1).

Proteolysis in Mitochondria

As in the cytosol and nucleus, proteins in mitochondria also have distinct half-lives and mitochondria can selectively degrade abnormally folded proteins. Mitochondria as a whole can be selectively degraded in lysosomes by autophagy (a process called 'mitophagy'). Their degradation seems to be targeted by a ubiquitin-ligase, parkin, which is mutated in a form of Parkinson's disease. However, this process cannot account for the different turnover rates of regulatory or misfolded mitochondrial proteins. Since the matrix and the inner membrane of mitochondria are not accessible to cytosolic proteases, these sites harbor their own proteolytic system, which consists of several evolutionarily conserved ATP-dependent proteases. This system has dual functions: it mediates the complete degradation of nonassembled or misfolded proteins, and it enables selective proteolysis of specific normal regulatory proteins that are important for the maintenance of mitochondrial function. The matrix of mammalian mitochondria contains two kinds of

Table 1 Disturbances of ubiquitin-dependent proteolysis in human disease

<i>Protein substrate</i>	<i>Disease</i>	<i>Mechanism</i>
<i>Increased proteolysis</i>		
p53	Cervical carcinoma	E6/E6-AP-mediated degradation of p53
p27 ^{Kip1}	Colorectal/breast Ca.	Enhanced degradation of a cell-cycle inhibitor
I κ B	Inflammation	Activation of NF κ B transcription factor
CFTR	Cystic fibrosis	Point mutation in CFTR, misfolding, and degradation through ERAD
MHC class I heavy chain	Cytomegalovirus infection	Downregulation of MHC class I by viral proteins
Most muscle proteins	Muscle atrophy, cachexia	Upregulation of an SCF E3, Atrogin-1, and the RING finger E3, MurF-1
<i>Decreased proteolysis</i>		
HIF1- α	von Hippel–Lindau disease	Mutation in SCF E3, VHL
ENaC	Liddle syndrome	Mutation in HECT E3, NEDD4
Receptor tyrosine kinases	Cancer	Mutation in RING finger E3, c-Cbl
Mitochondria	Parkinson's disease	Mutation in RING finger E3, Parkin
α -Synuclein	Parkinson's disease	Overexpression of HECT E3, Nedd4
Unknown	Angelman syndrome	Mutation in HECT E3, E6-AP
α 1-antitrypsin	Liver disease in some α 1-antitrypsin deficient patients	Decreased degradation of mutated α 1-antitrypsin by ERAD pathway
Epstein–Barr virus nuclear antigen 1 (EBNA1)	Epstein–Barr virus-associated malignancies	Immune evasion due to lack of EBNA1 Degradation

soluble proteases that are homologous to eubacterial Lon and ClpXP proteases (see below) and are responsible for degradation of matrix proteins. The mitochondrial inner membrane of all eukaryotic cells has two proteases that belong to the AAA superfamily of ATPases, termed 'i-AAA' and 'm-AAA'. These enzymes are complex structures with a native molecular mass of about 1 MDa composed of smaller subunits of 70–80 kDa. They expose their catalytic sites toward either the matrix or intermembrane space and have chaperone-like activity that is required for protein unfolding and subsequent degradation at proteolytic sites. Substrates of these proteases are proteins located in the inner membrane, and their degradation is essential for the maintenance of oxidative phosphorylation. Impaired function of these proteases causes neurodegeneration in humans and severe growth defects in yeast.

Proteolysis in Bacteria and Archaea

Roles of Proteolysis in Bacteria

Although bacteria and archaea do not have lysosomes, autophagic vacuoles, ubiquitin, or 26S proteasomes, they carry out very selective and highly regulated degradation of intracellular proteins. These prokaryotes contain several distinct ATP-dependent proteases that mediate the degradation of intracellular proteins. These enzymes serve functions similar to those of the protein degradation apparatus in eukaryotic cells. Bacteria selectively destroy abnormal proteins, including those arising from mutations, gene fusions, misfolding, chemical damage, or genetic engineering. In fact, successful expression of many recombinant proteins in *Escherichia coli* has been hampered by the action of these enzymes, and several bacterial strains lacking some of these proteases have been developed to increase the stability of cloned foreign proteins. Exposure to harsh environmental conditions, such as high temperature (heat shock), induces the genes which encode several molecular chaperones and the ATP-dependent proteases (Lon, ClpP, and HslUV) to

refold or degrade unfolded proteins that may be generated and protect against the buildup of these potentially toxic polypeptides. During exponential growth, most bacterial proteins are quite stable entities. However, even during normal growth, certain polypeptides with major regulatory functions are degraded very rapidly. For example, the specific component of bacterial RNA polymerase, so called sigma factor σ^{32} , has a half-life of a few minutes in *E. coli* under normal conditions, but it becomes transiently stabilized during heat shock, when it mediates the transcription of heat shock genes. A general enhancement of protein breakdown occurs in nongrowing cells deprived of nutrients in order to provide the starving organism with a source of amino acids for new protein synthesis or energy production. In many Gram-positive bacteria, prolonged starvation triggers sporulation, which is also accompanied by the marked degradation of most normal cellular proteins to provide amino acids for the expression of spore-specific genes.

Bacterial ATP-Dependent Proteases

Many eubacterial and archaeal ATP-dependent proteases are ancestors of more complex eukaryotic enzymes. Archaea and actinomycetes, unlike most eubacteria, for example, contain proteasomes that have similar architecture as eukaryotic 20S proteasomes, but are composed of 14 copies of a single α and a single β subunit. These particles function in protein breakdown in association with the ATPase complex, PAN, a hexameric-ring structure that is homologous to the six ATPases found in the base of the 19S component of eukaryotic proteasome. PAN has the capacity to unfold globular proteins and promote their entry into the 20S particle. The major ATP-dependent proteases in eubacteria are the cytoplasmic, the serine proteases La/Lon, 'caseinolytic proteases' ClpAP and ClpXP, the cytoplasmic threonine protease HslUV, and the inner membrane zinc-metalloprotease FtsH. These proteases

all have homologs in eukaryotic mitochondria of some species (see above). Bacterial ATP-dependent proteases are multimeric enzymes (400–700 kDa) that have distinct substrate specificities and subunit composition. They are composed of proteolytic domains and regulatory ATPase domains (e.g., Lon and FtsH) or separate regulatory ATPase complexes (e.g., ClpA, ClpX, and HslV), which actually determine substrate specificities. The simpler proteases, La/Lon and FtsH, contain these two domains in a single polypeptide chain. Lon consists of six identical 87-kDa protein subunits and was the first ATP-dependent protease described (by Chung and Goldberg in 1981). Other proteases are structurally closer to the eukaryotic 20S proteasomes (such as HslUV or ClpP), but their proteolytic subcomplexes are smaller. For example, the HslUV contains a central proteolytic chamber (HslV) composed of two hexameric rings with the active sites facing inward. Two ring-forming HslU complexes have ATPase activity and associate with proteolytic HslV cylinders on both ends to form a four-ring 20S proteasome-like particle capable of binding, unfolding, and degrading bacterial proteins. Besides proteases, the degradation of many proteins *in vivo* also requires chaperones of the Hsp70 and chaperonin (GroEL) families as cofactors that serve in the recognition of unfolded substrates. Like the proteasome, these ATP-dependent proteases generate short peptides of 10–40 amino acids, and they are degraded to amino acids by energy-independent cytosolic peptidases.

Selection of Substrates

Because bacteria lack ubiquitin and any homologous mechanism for covalent modification of substrates to be degraded, the ATPase-ring components (e.g., HslU, ClpA, or ClpX) of bacterial proteases determine their substrate specificity. With some exceptions, the exact recognition motifs on bacterial proteins are not well defined. However, special sequences on the N- and C-termini of cell proteins have been identified that lead to their recognition by ClpXP and may become particularly important in conditions when overall protein degradation is accelerated. All bacteria selectively degrade prematurely terminated proteins. A specific transfer RNA (tRNA) incorporates the tagging peptide SsrA (11-residue stretch of amino acids) into nascent polypeptide chain if ribosomes are stalled. The presence of an SsrA tag at the C-termini of a protein leads to its rapid hydrolysis by ClpXP and FtsH proteases. In addition to this recognition motif, in the case of multiprotein complexes, some proteins become substrates if present in cells without their natural binding partners, because the motifs that are recognized may be more accessible. Finally, chaperones may also provide some assistance in increasing susceptibility of substrates to bacterial proteases.

Targeting Proteolysis for Drug Development

Although a number of lysosomal diseases are known, the major ones are not due to defects in lysosomal proteases but rather

to failure to degrade polysaccharides or lipids due to lack of a specific lysosomal hydrolase. Commonly, these diseases are called 'lysosomal storage diseases' because undegraded material progressively accumulates in lysosomes. A number of major malignant, neurological, metabolic, and viral diseases are caused by the gain or loss of function of the ubiquitin–proteasome proteolytic system (Table 1). Since the disturbances in the ubiquitin–proteasome system underlie the pathogenesis of many human diseases, efforts to develop drugs that target this system are being pursued. The proteasome inhibitors are the first success in these efforts. In fact, the inhibitor, Bortezomib/Velcade, has proved to be very effective in the treatment of multiple myeloma, a cancer of the plasma cells. This agent has prolonged the lives of thousands of patients and its wider applications and other proteasome inhibitors are under intense investigation. However, more selective and more effective therapies are desirable, and efforts to develop small molecule inhibitors that target events upstream of proteasomes (e.g., ubiquitin ligation or deubiquitination and substrate recognition) may eventually allow the stabilization of desirable proteins or the clearance of specific pathogenic proteins.

Glossary

Amyloid A polymeric and fibrous form of a protein, usually formed by polypeptides that have undergone unfolding or misfolding.

Domain A compact structure composed of 50–150 amino acid residues that can fold independently of other parts of a protein.

Folding intermediate A partially folded conformational state that may form transiently during the conversion of an unfolded protein to the native state.

Molten globule A partially folded state that is characterized by the presence of regular secondary structure (usually

α -helices), but lacking well-defined interactions between side chains distant in the sequence.

Native state The well-defined folded structure of a protein usually associated with biological activity.

Unfolded state An ensemble of rapidly interconverting conformations with little or stable structure, usually generated by incubating a native protein with a denaturant or at elevated temperature. *In vivo*, polypeptides that have not yet folded into their native conformations may resemble artificially unfolded proteins.

Introduction

The folding and assembly of newly synthesized proteins represents a key step in the expression of genetic information, in which one-dimensional information is converted into three-dimensional structure. The central importance of this process has long been recognized, and a wide variety of approaches – experimental, theoretical, and computational – have been applied to studying folding both *in vitro* and *in vivo*. The goals of this research have been to understand the physical principles that determine the three-dimensional structures of proteins, as well as the biological aspects of the folding process, including the coupling of folding with other cellular processes and the consequences of misfolding.

The past decade has seen particularly rapid progress in the application of new experimental techniques, including single-molecule methods, to the study of protein folding, as well as advances in computational techniques. Although much remains to be learned, and some aspects are still controversial, there is a growing consensus regarding the general features of the folding process, and the goal of this article is to provide an overview of our current understanding of both the physical-chemical features of folding reactions and some of the biological aspects.

Another important advance in the past several years has been the recognition that many proteins, or parts of proteins, do not actually fold into stable structures. In some cases, these intrinsically disordered proteins do fold when they assemble with other molecules, but, in other cases, the protein may function without taking on a unique structure. While this class of proteins lies outside of the scope of this article, they are the subject of much current research and new biological implications are likely to emerge in the coming years.

Thermodynamics of Protein Folding

The thermodynamic stability of a protein is defined by the equilibrium between the native folded form and the highly

disordered unfolded state that is induced by elevated temperatures or chemical denaturants, such as urea or guanidinium chloride (GuHCl). Relatively small monomeric proteins, composed of 50–150 amino acid residues, typically unfold and refold efficiently and cooperatively, so that the process can be described as a simple equilibrium:

where N and U represent the native and unfolded states (Figure 1). While the native state usually has a well-defined three-dimensional structure, the unfolded state is best thought of as a broad distribution of rapidly interconverting conformations.

Under physiological conditions, the free-energy change for unfolding (ΔG_u) for a small monomeric protein typically lies in the range of 5–15 kcal mol⁻¹. This relatively small preference for the native protein reflects a delicate balance between three major factors: (1) a large loss of entropy as the chain is converted from a highly disordered state to an ordered state, (2) the transfer of nonpolar groups from an aqueous environment to a nonpolar environment in the protein interior, and (3) the formation of stabilizing interactions within the protein, including hydrogen bonds, salt bridges, and van der Waals interactions.

During the 1980s and 1990s, a great deal of effort was devoted to measuring the stabilities of genetically modified proteins in which single amino acid residues were replaced so as to delete one or a few stabilizing interactions. Taken together, these studies revealed that proteins are surprisingly tolerant of amino acid replacements, so that most mutations destabilize the native state by only a few kilocalories per mole or less, and substitutions that completely prevent folding are quite rare. Single substitutions that remove hydrogen bonds or nonpolar interactions cause, on average, roughly similar degrees of destabilization (usually of the order of 1–3 kcal mol⁻¹), implying that both types of interactions play important roles in stabilizing native proteins.

Figure 1 A cooperative protein unfolding–refolding transition. In a typical experiment, the native protein is incubated in solutions with increasing concentrations of denaturant such as urea or guanidinium chloride, and the fraction of unfolded molecules is determined by monitoring a spectroscopic signal, such as UV absorbance, fluorescence, or circular dichroism. For small monomeric proteins, the transition is usually highly cooperative, so that only the fully folded and unfolded forms are significantly populated and the fraction unfolded represents the relative concentrations of the two forms.

Folding Kinetics and Mechanisms

Levinthal's Paradox

Much of the work on folding mechanisms, both experimental and theoretical, has been motivated by the realization that the number of possible conformations accessible to a polypeptide chain is so immense that random sampling to find the structure with minimum free energy would take a ridiculously long time. For instance, if a chain is composed of 100 residues, and each residue can take on 10 possible conformations, then the total number of conformations is 10^{100} . If the various conformations are randomly sampled at a rate of 10^{13} per second (approximately the rate of rotation for a covalent bond), then the total time required to sample all of the conformations would be approximately 10^{80} years!

The calculation outlined above is frequently identified as the 'Levinthal paradox', in recognition of an insightful (but difficult to find!) 1969 paper by Cyrus Levinthal. Although this argument undoubtedly represents a great oversimplification, since many of the conformations assumed to be accessible to the chain will, in fact, be excluded by steric clashes among atoms in different residues, the calculation suggests that there must be some mechanism by which the search for the native conformation is limited.

Folding and Unfolding Rates

The rates at which different proteins fold and unfold vary tremendously. Even considering only relatively small proteins composed of a single domain, experimentally determined folding rate constants cover at least the range from 0.1 to 10^5 s^{-1} . While it might be expected that smaller and thermodynamically more stable proteins would fold the fastest, folding rates for unrelated proteins are poorly correlated with size or stability. Instead, a major determinant of folding rate appears to be the topological complexity of the native structure. While true topological knots are rarely found in folded proteins, different

structures vary with respect to the relative prevalence of interactions formed between closely and distantly spaced residues, and faster folding is often associated with topologies in which short-range interactions are more prominent. The physical basis for this correlation is not yet fully understood, but it strongly suggests that the rate-determining step in folding is associated with formation of the correct topology, as opposed, for instance, to formation of a local structure that then nucleates rapid folding of the rest of the chain.

Unfolding rates also vary greatly among different proteins and under different solution conditions. For some proteins, unfolding may be a surprisingly common event, even under physiological conditions. For instance, if the stability of a protein, ΔG_u , is 5 kcal mol^{-1} at 25°C , and the folding rate is 10^3 s^{-1} , the unfolding rate is predicted to be about 0.5 s^{-1} , so that 99% of the molecules in a population will undergo an unfolding event over a period of 10 s. Since unfolded proteins are typically much more sensitive to proteolysis than are folded proteins, spontaneous unfolding may be an important factor in determining the rate of protein turnover *in vivo*. Transient unfolding may also contribute to formation of aberrant structures, such as the amyloid fibers described later.

Folding Intermediates

Following in the tradition of biochemists who have successfully dissected other processes by identifying and characterizing discrete intermediates, many investigators have studied kinetic intermediates that accumulate transiently before protein-folding reactions reach equilibrium. While there is considerable diversity in the intermediates observed in the folding of different proteins, there appears to be common features among many of them.

Generally, the most easily detected intermediates form very rapidly (on the millisecond timescale or faster) after the unfolded protein is transferred to conditions that favor the native state. Often, the intermediate appears to contain

ordered secondary structure, especially α -helices, but there is little evidence of well-defined interactions between the side chains from different segments of the chain. The average dimensions of the chain in these intermediates typically lie between those of the native protein and the fully unfolded state in denaturants. Kinetic intermediates of this type also resemble partially unfolded states that can sometimes be generated under special solution conditions, including low pH for some proteins, or when a ligand (such as a metal ion or heme group) is removed from a native protein. These states, typically characterized by the presence of regular secondary structure but the absence of stable tertiary interactions, are described as molten globules.

As the most frequently observed partially folded states often interconvert rapidly with the fully unfolded protein, establishing whether or not these species are actually productive intermediates in folding, as opposed to products of side reactions, is quite difficult. As a consequence, there is presently a great deal of uncertainty and disagreement about the significance of these states for understanding folding mechanisms. Some authors believe that the formation of intermediates is important for limiting the search for the native conformation, while others argue that they are simply compact forms of the denatured state and do not play any special role in directing the chain toward the native state.

Transition States

It might seem surprising that the concept of a transition state, derived from studies of simple chemical reactions, could be usefully applied to a process as complex as protein folding. However, the folding kinetics of many proteins can be well described by a simple model in which the rate is determined by an equilibrium between the unfolded state and a higher energy state that is rapidly converted to the native conformation (Figure 2). The transition state can be envisioned as an

ensemble of partially ordered conformations that collectively have an equal probability of being converted to either the native or fully unfolded states.

By their very nature, transition states cannot be characterized directly by spectroscopic or other physical methods. Instead, their properties must be inferred from the results of experiments in which the kinetics of folding and unfolding are compared after perturbing either the structure of the protein or its environment. For instance, replacing an amino acid residue that contributes to the stability of the transition state is expected to increase the free-energy barrier for folding and, thereby, decrease the folding rate. On the other hand, a substitution that weakens an interaction that is present in the native protein but not the transition state is expected to increase the unfolding rate, without affecting the folding kinetics.

Detailed mutational analyses of transition states have now been carried out for several proteins. In general, it has been found that substitutions that destabilize the native protein most often increase the unfolding rate more than they decrease the folding rate, suggesting that most interactions that are present in the native protein are significantly weakened in the transition state. In addition, the relatively few residues that appear to play specific roles in stabilizing the transition state are often separated in the amino acid sequence but lie relatively close together in the native protein. These patterns suggest that the transition state ensemble may have a topology similar to that of the native protein, but not the network of cooperative interactions found in the fully folded structure (Figure 2). Poised with the correct topology, the molecules in the transition state can not only rapidly form these interactions, but also unfold rapidly.

Collectively, studies of folding intermediates and transition states over the past decade generally support a view of folding in which there is considerable breadth in the distribution of conformations representing different stages of the process, a view that has also emerged from computational simulations of folding. The conformational heterogeneity of these states makes detailed structural analysis very difficult, and there is much about folding mechanisms that still remains hidden from experimental view. More detailed descriptions of folding can, in principle, be derived from computational simulations, and the rapidly increasing power of computers and the development of new algorithms is now making it possible to carry out detailed molecular dynamics simulations of folding reactions. The past several years have seen much more extensive collaborations between experimentalists and computational scientists working on protein folding, and this development is already leading to important new insights into both the details of specific folding reactions and the general principles of the process.

Figure 2 Hypothetical energy profile for a protein-folding reaction. Currently available data, especially from mutational analyses of folding kinetics, suggest that the transition state for folding and unfolding is an ensemble of conformations that possess much of the topology of the native protein, but in which many of the native interactions are missing or weakened. The transition state ensemble is poised to fold completely or unfold rapidly.

More Complex Folding Reactions

Although the great majority of protein-folding experiments and simulations has been carried out with small monomeric proteins, most proteins found in nature are larger and have more complex structures. Most polypeptides form multiple domains when they fold, and many assemble into structures composed of multiple subunits. In addition, some proteins are stabilized by

disulfide bonds, which are formed during the folding process, and others contain tightly bound ligands such as metal ions, heme groups, or cofactors required for enzyme activity.

Proteins with Multiple Domains

Early in the study of protein structure, it was recognized that most proteins composed of more than 100–200 amino acid residues are typically organized into domains in which segments of 50–150 residues are folded into compact structures that are relatively independent of one another. Although a precise definition of a domain is somewhat elusive, the organization of a protein into substructures is often quite apparent from inspection of the three-dimensional structure or by computer analysis (Figure 3). Experimentally, domains can often be defined by limited treatment with a protease, since the polypeptide segments separating domains are usually much more sensitive to digestion than the regions within domains. The functions of larger proteins are often divided among their substituent domains, with different domains typically interacting with different molecules. It is clear from comparisons of protein structures and sequences that the same domains have frequently been exchanged among different proteins by genetic recombination, and the domain architecture of a protein can often be deduced by comparison of its sequence with those of known domains.

Figure 3 Domain structures of two proteins. In each drawing, the domains are distinguished by color. (a) Two domains of a cellular adhesion molecule, neuroglian from *Drosophila melanogaster*. The intact protein contains nine other domains, three of which are similar to the two shown here, which are members of the fibronectin III domain family. (b) Ferredoxin reductase from spinach chloroplasts. In this structure, the two domains do not resemble one another and interact much more extensively than the two fibronectin domains shown in (a). (a) Drawn from the atomic coordinates of entry 1CFB in the Protein Data Bank. (b) Drawn from the atomic coordinates of entry 1FNB in the Protein Data Bank. The drawings in Figures 3 and 4 were made with the computer programs MOLSCRIPT and Raster3d.

When isolated from the rest of the protein, individual domains typically retain their native conformations and undergo cooperative unfolding transitions similar to those observed with smaller proteins. Furthermore, when the intact protein unfolds, the resulting spectroscopic signals often resemble a simple superposition of those for the isolated domains. In these cases, the domains appear to be truly independent, and studying their folding individually likely provides a good description of the folding mechanism for the intact protein. In other cases, however, the domains may interact more intimately, so that the entire structure unfolds cooperatively. The folding mechanism may also involve interactions among the domains before their individual structures are fully defined.

A relatively recent advance has been the use of single-molecule techniques, especially atomic force microscopy and laser traps, to monitor the mechanically induced unfolding (stretching) of multi-domain proteins. These studies have provided direct evidence for the modular structures of these proteins, as well as new insights into the elastic properties of proteins.

Disulfide-Coupled Folding

Many proteins, especially among those that function extracellularly, are stabilized by disulfide bonds, covalent bonds between the sulfur atoms of cysteine (Cys) residues that are formed by oxidation of the Cys thiol groups. *In vivo*, disulfide bonds are formed in concert with folding after the polypeptide is synthesized and translocated to either the lumen of the endoplasmic reticulum or the intermembrane space of mitochondria in eukaryotic cells, or the periplasmic space of bacteria. In all three of these compartments, disulfides in the newly synthesized proteins are formed by exchange with disulfides present in special proteins that act as catalysts of the process.

In a landmark series of experiments in the early 1960s, C B Anfinsen and his colleagues demonstrated that the four disulfide bonds of bovine ribonuclease A could be induced to reform spontaneously *in vitro* after the protein had been fully reduced and unfolded in urea. The regeneration of active enzyme, even after the covalent constraints on the polypeptide chain had been broken, provided a particularly clear demonstration that the three-dimensional structure was encoded by the amino acid sequence.

When refolding of a reduced protein is initiated, disulfides typically form quite randomly, leading to a distribution of molecules with different disulfide bonds that can rapidly interconvert. The formation of an initial disulfide, however, can often favor conformations that then bring other Cys residues together to form a second disulfide. These conformations can also be stabilized by noncovalent interactions, leading to a high degree of cooperativity among the various interactions.

As more of the three-dimensional structure forms and is stabilized by additional disulfides, the ability of the molecule to undergo additional disulfide formation and rearrangement steps can become severely constrained, leading to the accumulation of species that contain most or all of the native structure but lack one or more disulfides. *In vivo*, disulfide isomerase enzymes can catalyze the slow rearrangements necessary to convert the trapped molecules to the native form, or may promote alternative pathways that avoid the kinetic traps.

Ligand Binding

Yet another way in which folding can be influenced is through the binding of ligands such as metal ions or prosthetic groups. In most cases, ligands have little tendency to interact with unfolded proteins, so that the molecule must be at least partially folded before the interaction takes place. A thermodynamic consequence of this is that the stability of the folded protein is enhanced by the presence of ligand and depends on both the affinity of the interaction and the concentration of free ligand in solution. If the binding site is formed only when the protein is fully folded, binding may not greatly alter the folding process either *in vitro* or *in vivo*. On the other hand, interactions of ligands with partially folded species could favor some pathways over others and might prevent aberrant interactions with other molecules.

Proteins that require the binding of reactive metal ions, such as those of iron, copper, or nickel, present a particularly interesting problem during folding *in vivo*. As these ions are highly toxic, their free concentrations are maintained at very low levels by transport and storage proteins that bind tightly to them. The ions must then be transferred to other proteins for which they are required for activity, such as catalysis. Although the details are not yet well understood, it appears that quite elaborate systems involving multiple transfer proteins have evolved to facilitate the safe transfer of ions to their proper sites.

Some prosthetic groups, such as the heme group of cytochrome *c*, are covalently bonded to the polypeptide chain. For these proteins, the covalent modifications, and the enzymes that catalyze them, are likely to be intimately involved in the folding process.

Molecular Chaperones

While many proteins refold spontaneously and efficiently *in vitro*, it is now known that folding *in vivo* is often facilitated by molecular chaperones, proteins that interact transiently with the polypeptide chain and either promote folding or decrease the likelihood of nonproductive interactions. The best-characterized molecular chaperones include members of the GroEL/GroES and HSP70 families. Members of both groups utilize the energy of adenosine triphosphate (ATP) hydrolysis to couple conformational changes in the chaperone to a cycle of substrate protein binding and release, during which the substrate folds into its native conformation. Other examples of molecular chaperones include the catalysts of disulfide formation and exchange and the metal chaperones mentioned above. Although the chaperones can increase the efficiency of folding, it does not appear that they influence the final structure. Their discovery, therefore, has not required a revision of the fundamental idea that the folded structure of a protein is determined by the amino acid sequence. However, we now have a much greater appreciation of protein folding as a biological process that is intimately coupled to numerous other intracellular events.

Assembly of Oligomeric Proteins

Only a minority, perhaps 20%, of proteins contain a single polypeptide chain, the remainder being assemblies of multiple

subunits. Dimeric and tetrameric complexes are the most common, but assemblies of 20–50 subunits are also known. The assembly of subunits into larger complexes can offer a variety of functional advantages, including mechanisms for regulating the activities of enzymes, the creation of novel binding sites at subunit interfaces, and the coordination of multiple related functions in a single complex.

Multimeric proteins can be assembled from a single type of subunit, resulting in a homooligomer, or they can be heterooligomers composed of two or more different kinds of chains. Quite often, these structures are highly symmetrical. Dimers of identical polypeptide chains are especially common, and dimers are often the basic units of higher-order structures, such as tetramers, hexamers, etc.

The types of interactions that hold the subunits of oligomers together are essentially the same as those found within monomeric proteins or the individual subunits themselves, including hydrogen bonds, ionic, and van der Waals interactions. However, surveys of the distribution of different interaction types in various protein environments have revealed some differences between those found between and within subunits, with ionic interactions being more common in the interfaces between subunits.

Many oligomeric proteins have been successfully refolded and assembled *in vitro* after being unfolded in denaturants, though the reactions are often slower and less efficient than the folding of small monomeric proteins. In some cases, the rate of refolding is dependent on protein concentration, indicating that the rate is determined by intermolecular association reactions. In other cases, the reaction kinetics are limited by intramolecular rearrangements that occur either before or after subunit association.

These differences in kinetic behavior suggest that oligomeric structures may form by a variety of mechanisms. In order to assure specificity, the initial interactions between two subunits presumably require that one or both of them first takes on at least a partially folded conformation. In some cases, the interaction may only occur after the subunits are fully folded, so that folding and assembly are distinct processes. This mechanism requires that the individual subunits have compact self-contained structures similar to those of monomeric proteins, as epitomized by the four subunits of hemoglobin (Figure 4(a)). For some oligomers, however, the subunits form extensive interactions with one another along large interfaces that make it unlikely that the individual subunits could fold completely before assembling. In extreme cases, the subunits are actually wrapped around one another, as observed in the structure of the tailspike protein of bacteriophage P22 (Figure 4(b)). These more complex arrangements of subunits likely lend the structures a great deal of kinetic stability, but possibly at the cost of more complex folding mechanisms involving unstable intermediates that may be prone to aberrant misfolding or aggregation reactions.

Protein subunits can also form complexes with either ribose nucleic acid (RNA) or deoxyribose nucleic acid (DNA), as in ribosomes or the nucleosomes of eukaryotic chromatin. These interactions are often mediated by electrostatic interactions between Arg or Lys residues of the proteins and the negatively charged phosphate groups of the nucleic acids, but nonpolar interactions can also play a role. Just as protein subunits can

Figure 4 Subunit structures of two proteins. (a) Human hemoglobin, a tetramer formed of two types of subunits, colored green and blue in the drawing. Each of the subunits is a compact and self-contained structure. The heme groups associated with each of the four chains are also shown in a ball-and-stick representation. Drawn from entry 2HHB in the Protein Data Bank. (b) A fragment of the trimeric tailspike protein of bacteriophage P22. The intact protein includes an additional domain at the amino-terminus of the chain (at the lower left corner of the drawing), by which the tailspike binds the rest of the virus particle. In this structure, the individual subunits interact extensively with one another and are intertwined, requiring an assembly mechanism in which the chains do not fold completely until after they have associated. Drawn from entry 1TSP of the Protein Data Bank.

associate with one another either before or after being fully folded, the formation of protein–nucleic acid complexes may involve folding processes that take place after association as well as before.

Protein Misfolding and Disease

Over the past decade, defects in protein folding or assembly have become recognized as important factors leading to a variety of diseases. These include cystic fibrosis, some forms of emphysema, and a large number of conditions associated with the formation of long fibrillar protein structures, the amyloid diseases. Mutations that destabilize the native protein may lead to premature degradation or the formation of aberrant assemblies, which, in turn, may lead to a deficiency for

an important activity or the formation of structures that are actually toxic.

At present, the amyloid diseases appear to be the most important category of folding pathologies. Diseases associated with amyloid formation include neurodegenerative conditions such as Alzheimer's and Parkinson's diseases and amyotrophic lateral sclerosis, as well as several systemic amyloid diseases. In an intriguing minority of diseases, particles of amyloid fibers from one individual can promote fibril formation in another, providing a mechanism of infectivity that does not involve either bacteria or viruses. These infectious agents have been named prions and the diseases they are associated with include scrapie (in sheep) and bovine spongiform encephalopathy (BSE or mad cow disease), as well as the human disease Kuru and a variant of Creutzfeldt–Jacob disease that is believed to be derived from BSE. However, the transmission of an altered physiological state by a protein amyloid is not at all restricted to mammals, as a very similar process has been found in the unicellular yeast, *Saccharomyces cerevisiae*, and this discovery has provided an important experimental system for analyzing the prion phenomenon.

A surprisingly large number of proteins are now known to form amyloid-like fibers under at least some *in vitro* conditions, and it may be that the ability to form these structures is a nearly universal property of polypeptide chains. Remarkably, there is a great deal of similarity among the structures of fibers formed from proteins with very different sequences and native structures. The fibers are generally about 50–100 Å in diameter and a fraction at least of the polypeptide chain has a β -strand conformation, with the strands oriented so that their backbones are approximately perpendicular to the fiber axis.

Fibril formation *in vitro* is typically favored by conditions that destabilize the normal folded conformation but do not fully unfold and solubilize the polypeptide. *In vivo*, conversion to the amyloid state may be promoted by inherited mutations, environmental stress, or, as noted above, seeding by an existing fibril fragment. At present, it is difficult to establish a clear mechanistic link between fibril formation and the physiological changes associated with amyloid diseases. In some cases, the amounts of protein deposited in fibrils are so large, as much as several kilograms in some patients, that these structures are clearly able to interfere with normal organ function. Smaller fibrils may similarly be toxic at the cellular level. In other cases, it may be that diversion of essential proteins into fibrils leads to functional deficiencies.

Although most known examples of amyloid formation are associated with detrimental effects, there is a growing list of cases in which the amyloid form of a protein has a distinct function. These include regulation of gene expression by the *Saccharomyces* proteins mentioned above, formation of melanin granules in the human epidermis, and storage of proteins in secretory granules.

As amyloid fibril formation usually competes with normal folding, investigators are actively pursuing the possibility that these diseases might be prevented or treated by agents that favor productive folding or disfavor unfolding, for instance, by binding to the native structure. These developments provide a vivid link between the basic science of protein folding and an important medical problem.

Glossary

Oxa1 translocase Protein complex of the inner membrane of mitochondria that facilitates membrane insertion of both nuclear and mitochondrially encoded proteins.

Preprotein Precursor form of a mitochondrial protein; preproteins often contain presequences that have to be removed by mitochondrial processing peptidases.

Presequence Typically N-terminal extension on a protein that serves as mitochondrial targeting signal.

Translocase of the outer membrane (TOM) Multisubunit translocation complex of the outer membrane of mitochondria consisting of receptor subunits and a protein-translocating channel.

Translocases of the inner membrane (TIMs) Oligomeric translocation complexes of the inner membrane of mitochondria.

Mitochondria are essential organelles of eukaryotic cells that accommodate nearly 10–20% of the cellular proteome. They are made up of two membrane systems that divide the organelle into two aqueous subcompartments: the intermembrane space, between the outer and the inner membrane, and the matrix, which is enclosed by the inner membrane. The vast majority of mitochondrial proteins are encoded by the nuclear genome and synthesized on cytosolic ribosomes as precursors (also called preproteins). These proteins contain targeting information for specific sorting of each polypeptide to its respective mitochondrial subcompartment. Protein import into mitochondria is achieved by the concerted action of translocation complexes located in both membranes of the organelle.

Mitochondrial Targeting Signals

Targeting signals direct mitochondrial precursor proteins to their particular destination in the organelle. In addition, these sequences can prevent folding of precursor proteins in the cytosol and thereby maintain them in a transport-competent conformation. Proteins of the mitochondrial matrix and many inner membrane proteins are made with N-terminal extensions which are proteolytically removed by proteases following translocation into the mitochondrial matrix. These matrix targeting signals (MTSs) are referred to as presequences. Most mitochondrial proteins carry such N-terminal presequences. In addition, less defined internal signals are used for mitochondrial targeting, typically by proteins of the outer membrane, the intermembrane space, and by some inner membrane proteins.

Presequences

Presequences generally comprise 15–80-amino-acid residues that have the potential to form amphipathic α -helices with one hydrophobic and one positively charged face. These signals are both necessary and sufficient for mitochondrial targeting. The addition of presequences to unrelated proteins typically leads to targeting of the fusion proteins to mitochondria. The MTSs direct the extended polypeptide in an

N-to-C-direction across both mitochondrial membranes. Examples were reported in which MTSs are located not at the N-terminus but at the C-terminus or in the interior of a preprotein. In the latter case, the internal signal forms an amphipathic hairpin loop which precedes import of the N- and C-terminal parts of the preprotein. In many cases, N-terminal presequences can be identified by computer algorithms which predict the intracellular location of proteins.

Internal Targeting Signals

Many mitochondrial proteins contain less defined targeting signals which are a part of the mature polypeptide. These are referred to as internal signals. For example, proteins of the solute carrier family of the inner membrane are made up of modules of pairs of transmembrane domains which are imported as loop-like structures. The regions flanking these transmembrane domains are critical for the uptake of these proteins by the mitochondria. The nature of these signals and how they are deciphered are, however, not well understood.

Proteins of the outer membrane are often anchored in the lipid bilayer by terminal transmembrane domains. A moderate degree of hydrophobicity and flanking positive charges specify these proteins for mitochondria and differentiate them from other tail-anchored proteins of the cell. Sorting of β -barrel proteins into the outer membrane by the TOB/SAM (topogenesis of mitochondrial outer-membrane β -barrel proteins/sorting and assembly machinery) complex is directed by a specific signal sequence close to their C-terminus.

Little is known about the targeting information that directs proteins into the intermembrane space of mitochondria. Many of these proteins are small and bind cofactors such as metal ions or heme. Several proteins of the intermembrane space contain structural disulfide bonds. The oxidation of cysteinyl thiols is mechanistically coupled to the import of these proteins. The amino acid sequences in proximity to these cysteine residues follow specific patterns and represent sorting signals to the intermembrane space. These signatures are referred to as mitochondrial intermembrane space sorting sequences (MISSs) or intermembrane space-targeting signals (ITSSs).

Transport to and across the Outer Membrane

A number of cytosolic factors were identified that bind to mitochondrial preproteins following their synthesis. Among these factors are members of the general chaperone system, such as Hsp70 and Hsp90, and components that appear to play a more specific role in the targeting of mitochondrial proteins. These factors keep preproteins in an import-competent conformation and accompany them to the surface of mitochondria.

The Translocase of the Outer Membrane

The outer membrane harbors surface receptors that expose binding sites for MTSS to the cytosol (see Table 1). These receptors are part of a multimeric protein translocase, called the translocase of the outer membrane (TOM) complex. In fungi, the TOM complex comprises the receptor subunits Tom70, Tom22, and Tom20. These surface receptors direct preproteins to the so-called 'general insertion pore' of the outer membrane, the main constituent of which is Tom40. Tom40 is thought to be present in a β -barrel structure in the outer membrane, similar to bacterial porin proteins, and by oligomerization forms protein-conducting channels. Three small additional subunits, Tom5, Tom6, and Tom7, appear to play a role as structural components and might be involved in regulating the interaction of the receptors with Tom40. In mammals, the TOM complex consists essentially of a similar set of homologous components. High-resolution electron microscopy of isolated TOM complexes revealed two membrane-traversing cavities of 2.2 nm, which most likely represent the preprotein-conducting channels in the outer membrane. Following translocation of preproteins through the general insertion pore, preproteins associate with the *trans* site of the TOM complex. This *trans*-binding site is formed by the intermembrane space domains of Tom40 and perhaps Tom22. An increasing binding affinity from *cis* to *trans* sites on the TOM complex was suggested to drive translocation of preproteins across the outer membrane into the intermembrane space.

Insertion into the Outer Membrane

In addition to its translocation function, the TOM complex facilitates the insertion of proteins into the lipid bilayer of the outer membrane (Figure 1, pathway 1). Although the molecular mechanism of this process is poorly understood, a critical role of the TOM complex was shown for membrane integration and assembly of TOM subunits, as well as for the insertion of other outer membrane proteins. The most abundant protein of the outer membrane, porin, and several tail-anchored proteins, such as the apoptosis regulator B-cell lymphoma 2 (bcl-2), require cytosolic receptor domains of TOM subunits for mitochondrial targeting. However, whereas integration of porin requires the general insertion pore in the TOM complex, bcl-2 was reported not to use the TOM channel.

β -Barrel proteins such as porin and the pore-forming constituent of the TOM complex, Tom40, are inserted into the outer membrane from the intermembrane space (Figure 1, pathway 2). Membrane insertion of these proteins is mediated by a specialized complex, named TOB or SAM complex. This insertion machinery is conserved from bacteria to mitochondria

Table 1 Components of the mitochondrial import machinery

Components		Function
<i>Fungi</i>	<i>Mammals</i>	
<i>Outer membrane, TOM complex</i>		
Tom70, Tom71	Tom70	Surface receptor
Tom40	Tom40	Pore formation
	Tom34	Surface receptor, Tom70 homolog
Tom22	Tom22	Surface receptor
Tom20	Tom20	Surface receptor
Tom7	Tom7	Structural or regulatory component
Tom6	Tom6	Structural component
Tom5	Tom5	Receptor function

Figure 1 Protein import pathways in mitochondria. (1) Proteins of outer membrane that contain α -helical transmembrane domains are synthesized on cytosolic ribosomes and bind to the receptor subunits of the TOM complex before they are integrated into the outer membrane or further transported into the other mitochondrial subcompartments. (2) β -Barrel proteins of the outer membrane are initially transported through the TOM complex before they insert into the outer membrane in a process facilitated by the TOB/SAM complex. (3) Many proteins of the intermembrane space contain disulfide bonds. These are formed by interaction of these proteins with the oxidoreductase Mia40. Mia40 is maintained in a functional, oxidized state by the sulfhydryl oxidase Erv1. (4) Members of the solute carrier family and some Tim subunits traverse the outer membrane, forming loop-like structures. They are escorted to the TIM22 translocase in the inner membrane by complexes of small Tim protein complexes in the intermembrane space. (5) Matrix proteins contain presequences that mediate translocation through the TOM channel and interact with the TIM23 complex in the inner membrane. The presequences are transported across the inner membrane in a membrane potential-dependent manner, and removed by processing peptidases. Further translocation across the inner membrane requires the action of the ATP-dependent import motor. Matrix proteins then fold with the assistance of molecular chaperones. (6) Single-spanning inner membrane proteins can be arrested at the TIM23 translocase and laterally integrated into the lipid bilayer of the inner membrane. (7) Conservatively sorted proteins are first transported into the matrix and form sorting intermediates bound by mtHsp70. Subsequently, these proteins are inserted into the inner membrane in a membrane potential-dependent reaction. The inner membrane protein Oxa1 is required for membrane integration of several of these proteins.

and chloroplasts. Its central component, Tob55/Sam50, is also of β -barrel structure and homologous to the Omp85 protein that is essential for outer membrane biogenesis in prokaryotes.

Translocation into the IMS

The intermembrane space is a compartment of very small volume since the outer and inner membranes are in very close proximity. Only a relatively small number of components

of the intermembrane space are known, most of which are required for mitochondrial biogenesis or have a function in energy metabolism. A prominent example is cytochrome *c*, which plays a role in apoptosis apart from its function in shuttling electrons between complexes III and IV. Apocytochrome *c* is imported by the TOM complex and associates in the intermembrane space with the protein cytochrome *c* heme lyase (CCHL). CCHL represents a docking site for apocytochrome *c* and catalyzes its conversion to holocytochrome *c* by covalent addition of a heme group. Holocytochrome *c* is not able to

traverse the TOM channel and, thus, remains in the intermembrane space. Like cytochrome *c*, many intermembrane space proteins bind cofactors and may be imported by a similar mechanism.

Many proteins of the intermembrane space contain cysteine residues which form structural disulfide bonds. The import of these proteins relies on a specialized thiol oxidation machinery that consists of the oxidoreductase Mia40 and the sulfhydryl oxidase Erv1 (Figure 1, pathway 2). Mia40 serves as a receptor that traps incoming substrate proteins and facilitates their oxidation. Erv1 maintains Mia40 in the oxidized state. Both proteins are highly conserved among eukaryotes.

Another group of intermembrane space proteins is synthesized with N-terminal presequences followed by sorting signals. These signals are arrested at the level of the inner membrane. Proteases such as the Imp1/Imp2 protease at the outer face of the inner membrane then cleave after the sorting signals and the mature parts of the precursors are released into the intermembrane space. These sorting signals can be transplanted to unrelated passenger proteins to direct these into the intermembrane space. Examples of this type of proteins are cytochrome *b*₂ or cytochrome *b*₅ reductase.

A further group of soluble proteins of the intermembrane space is made without a cleavable and so-far-identified internal targeting signal. Examples are the cytochrome *c* and *c*₁ lyases, adenylate kinase and creatine kinase.

Translocation into the Matrix

The mitochondrial matrix contains a large number of proteins, many of which fulfill important functions in metabolic processes, energy production, or the replication and expression of the mitochondrial genome. These proteins in most contain N-terminal presequences and are imported on a common import route (Figure 1, pathway 5).

The Translocase of the Inner Membrane of Mitochondria 23 Complex

The translocase of the inner membrane of mitochondria 23 (TIM23) complex consists of Tim50, Tim23, Tim21, and Tim17, proteins which are integrated into the inner membrane exposing functional domains to the intermembrane space side and Tim44, Tim16/Pam16, Tim14/Pam18, and Pam17 which are associated with the former constituents at the matrix face. Tim23 and Tim17 share sequence similarity and are likely to form the translocation pore in the inner membrane. In yeast, the N-terminus of Tim23 protrudes into the outer membrane and thereby may mediate contact of the TOM and the TIM23 translocases. Tim50 exposes a large domain to the intermembrane space and plays a role in guiding preproteins from the TOM to the TIM23 complex. The transfer of preproteins from the TOM to the TIM23 complex was suggested to be further regulated by Tim21. Binding of the presequence to the TIM23 complex was proposed to lead to a membrane potential-dependent gating of the channel, which allows the presequence to traverse the inner membrane. This translocation reaction is driven by the membrane potential, which probably supports the movement of the positively

charged presequences to the negatively charged matrix face of the inner membrane. In the matrix, the presequences are bound by the chaperone mtHsp70, which prevents backsliding of the translocation intermediate. MtHsp70 is recruited to the TIM23 translocase by the Tim44 subunit of the complex which warrants a high activity of mtHsp70 at the exit of the TIM23 channel and, thus, the efficient trapping of the incoming polypeptide. The adenosine triphosphate (ATP)-dependent interaction of mtHsp70 with the preprotein is regulated by two DnaJ-like cofactors Tim16/Pam16 and Tim14/Pam18, and by the nucleotide exchange factor, mtGrpE/Mge1. This process is responsible for the ATP dependence of the mitochondrial import process. Binding of the preprotein to mtHsp70 is followed by the release of mtHsp70 from Tim44. Spontaneous unfolding of segments of the precursor on the outer face of the outer membrane, reversible sliding of the polypeptide chain in the TOM-TIM23 translocation channel, and repeated cycles of trapping by and release from mtHsp70 lead to vectorial movement of the preprotein into the matrix. This mechanism is referred to as Brownian ratchet model of mitochondrial protein import, as the essential role of mtHsp70 is to prevent backsliding of the preprotein. It was suggested that in addition to its trapping function, mtHsp70 undergoes an intramolecular conformational change and thereby mechanically pulls the bound preprotein into the matrix. The validity and significance of this motor model are still under debate.

Protein Folding and Assembly

In the matrix, the presequences are typically removed by processing peptidases. The mitochondrial processing peptidase (MPP) consists of two conserved subunits which convert most matrix proteins into their mature form. In addition, some preproteins are further processed by the mitochondrial intermediate peptidase, which removes another eight N-terminal amino acid residues. The mature proteins are then allowed to fold into their native structure. This process is facilitated by mtHsp70 which cooperates in this process with the DnaJ homolog Mdj1/hTid. Folding of some matrix proteins depends on the chaperonin complex formed by Hsp60 and Hsp10, which is homologous to the GroEL/GroES complex of the bacterial cytosol.

Protein Insertion into the Inner Membrane

The inner membrane contains a large number and diversity of proteins and belongs to the protein-richest membranes of eukaryotic cells. Inner membrane proteins reach their destination on several different insertion routes. At least three different pathways are known that lead precursor proteins into the inner membrane.

Insertion via the TIM23 Translocase

A number of monotopic inner membrane proteins are integrated into the inner membrane following translocation arrest at the level of the TIM23 complex (Figure 1, pathway 6). This sorting route was named the 'stop-transfer' pathway. Most of these proteins are of N_{in} – C_{out} topology, but some examples

were reported which are oriented in an $N_{out} - C_{in}$ topology by internal loop-forming presequences.

Insertion from the Matrix

Alternatively, proteins can be inserted into the inner membrane following complete translocation into the matrix (**Figure 1**, pathway 7). This transport pathway was denoted conservative sorting, since the process employs a bacterial-like insertion reaction from the matrix. The examples for this sorting path are inner membrane proteins of prokaryotic origin. Not only the direction of the membrane integration reaction resembles that in prokaryotes, but also the topogenic signals and the components that catalyze the insertion process. Conservatively sorted proteins adhere to the positive-inside rule according to which negative charges flanking the transmembrane segments are preferentially translocated across a membrane. A central player in the insertion process of these proteins is the inner membrane protein Oxa1 which is conserved from bacteria to mitochondria. Besides its role in the membrane integration of conservatively sorted proteins, the Oxa1 translocase mediates the insertion of mitochondrial translation products into the inner membrane.

Insertion via the TIM22 Translocase

A third group of inner membrane proteins is inserted by an alternative TIM complex, the TIM22 translocase (**Figure 1**, pathway 4). This pathway is used by members of the solute carrier family, a prominent member of which is the adenosine diphosphate (ADP)/ATP carrier, and by some TIM subunits. These proteins do not contain presequences but internal signals. Upon translocation through the TOM complex, these proteins associate with the hexameric Tim9·Tim10 and/or

Tim8·Tim13 complexes of the intermembrane space which belong to the family of 'small Tim proteins'. These complexes escort the hydrophobic precursor proteins from the TOM complex through the intermembrane space to the TIM22 complex. The TIM22 complex comprises the membrane-embedded subunits Tim54, Tim22, and Tim18 to which a Tim9·Tim10·Tim12 hexamer is associated. Tim22 is related to Tim17 and Tim23, and forms the translocation pore of the complex. Mutations in the human Tim8 homolog, DDP1, lead to the deafness dystonia (Mohr-Tranebjaerg) syndrome, a progressive neurodegenerative human disorder.

Glossary

Diacylglycerol The membrane-retained lipid backbone released from phospholipids following activation of appropriate phospholipases, enzymes that hydrolyze phospholipids. Diacylglycerol is considered a second messenger because it transfers information from stimuli such as hormones to protein kinase C, which transduces the signal by phosphorylating protein substrates.

Kinase The class of enzymes that covalently transfer phosphate from adenosine triphosphate (ATP) to hydroxyl groups of proteins.

Phosphorylation The covalent attachment of phosphate from the cellular energy currency, ATP to hydroxyl residues of proteins, a modification that changes the properties of the protein.

Protein kinase C (PKC) is a family of enzymes that has a central role in transducing information from external stimuli to cellular responses. Members of this family of serine/threonine kinases respond to signals that cause lipid hydrolysis. PKC isozymes phosphorylate an abundance of substrates, leading to both short-term cellular responses such as regulation of membrane transport and long-term responses such as memory and learning.

Historical Perspective

PKC was discovered in the late 1970s by Yasutomi Nishizuka and colleagues at Kobe University, Japan. Their initial discovery was of a constitutively active enzyme that required only Mg^{2+} for activity (and hence was named protein kinase M, PKM). Further studies revealed that PKM was a proteolytic product of a full-length enzyme; this enzyme was named PKC because its enzymatic activity could be released by a Ca^{2+} -dependent protease. The subsequent discovery that PKC is activated by the phospholipid hydrolysis product, diacylglycerol, was a major finding in biology: it provided the molecular mechanism for how lipid hydrolysis, discovered 25 years earlier to be triggered by stimuli such as acetylcholine, couples to cellular signaling pathways.

But the discovery that catapulted research on PKC to the forefront of cellular signaling was the finding that it is the receptor for the potent tumor-promoting phorbol esters. Phorbol esters are present in the milky sap exuded from plants of the Euphorbiaceae family; the oil from the seeds of one member of this family, in particular *croton tiglium*, has particularly strong irritant properties and, as such, has been used over the millennia for purposes as varied as poison for hunting arrows to medicinal purposes. In the 1960s, the active ingredient in the oil was found to be a family of diesters of the tetracyclic diterpene phorbol. Phorbol esters were shown to be extremely potent tumor promoters, and classic studies revealed that painting phorbol esters on the skin of mice allowed otherwise subthreshold amounts of carcinogens to promote tumors. The finding that PKC is the direct molecular target of phorbol esters placed this enzyme at the center of signaling pathways that control normal cell function and carcinogenesis.

PKC Family Members

There are 10 mammalian isozymes of PKC that share in common a carboxyl-terminal kinase domain linked to an amino-terminal regulatory moiety (Figure 1). The regulatory moiety, in turn, contains a number of functional modules and it is the composition of these functional modules that further defines the three subfamilies of the PKC isozymes. These modules are an autoinhibitory-pseudosubstrate sequence that maintains the enzyme in an inactive conformation, and one or two membrane-targeting modules that direct PKC to the membrane following generation of the appropriate second messengers. Specifically, the C1 domain binds diacylglycerol and phorbol esters and the C2 domain binds Ca^{2+} ; each event promotes the binding of the respective domain to membranes.

Conventional PKC isozymes (α , βI , βII , and γ), have a C1 and a C2 domain and respond to both diacylglycerol and Ca^{2+} . Novel PKC isozymes (δ , ϵ , η , and θ) have a C1 domain that binds diacylglycerol, but an impaired C2 domain that does not bind Ca^{2+} . These isozymes respond to increases in cellular diacylglycerol but not Ca^{2+} . Note that a change from a Tyr to Trp in the C1b domain of novel isozymes, compared to conventional isozymes, confers an order of magnitude higher affinity for diacylglycerol, allowing these isozymes to respond to signals that elevate only intracellular diacylglycerol. Atypical PKC isozymes (ζ and ι/λ) have an impaired C1 domain and no C2 domain and bind neither diacylglycerol nor Ca^{2+} . Rather, they have a PB1 domain that mediates protein:protein interactions. Thus, stimuli that elevate intracellular diacylglycerol activate conventional and novel PKC family members, with conventional isozymes being additionally regulated by Ca^{2+} . Atypical isozymes are regulated by other mechanisms such as phosphorylation and protein interactions.

PKC Phosphorylation

Before PKC is competent to signal, it must first be processed by a series of ordered phosphorylations. These phosphorylations depend on two kinases: the phosphoinositide-dependent

Figure 1 Primary structure and domain composition of protein kinase C family members. The amino-terminal regulatory moiety contains the autoinhibitory-pseudosubstrate sequence (green), the C1 domain, which binds diacylglycerol/phorbol esters (orange; present as a tandem repeat in conventional and novel protein kinase C isozymes), and the C2 domain, which binds Ca²⁺ (yellow). The C2 domain in novel protein kinase Cs and the C1 domain in atypical protein kinase Cs are non-ligand-binding variants. Atypical isozymes contain a PB1 domain that mediates protein:protein interactions (purple). The carboxyl-terminal catalytic moiety contains the kinase core which has three phosphorylation sites, one on the activation loop segment (pink circle) and two on the carboxyl-terminal tail (blue): the turn motif (orange circle) and the hydrophobic motif (green circle; the negatively charged amino acid glutamate (E) occupies the phospho-acceptor position of the hydrophobic motif in atypical protein kinase Cs). The second messenger sensitivity is shown on the right of each isozyme subgroup; note that novel isozymes have a 10-fold increased affinity for diacylglycerol compared to conventional protein kinase C isozymes, allowing them to respond to signals that elevate only diacylglycerol and not both diacylglycerol and Ca²⁺. The 3D structures of the domains are shown below the primary structure.

kinase, PDK-1, and the mammalian target of rapamycin (mTORC2) complex, which comprises the kinase mTOR, rictor, and a number of other interacting partners. These kinases have pivotal positions in cell signaling: PDK-1 catalyzes the activating phosphorylation to many other PKs, including the prosurvival kinase, Akt/PKB and mTORC2 plays an essential role in allowing Akt/PKB to become fully phosphorylated. Both kinases are necessary (but neither is sufficient) for the processing of PKC by phosphorylation, and lack of either one results in unphosphorylated PKC that is unstable and becomes degraded. Although the precise mechanism of phosphorylation is still being resolved, it appears that the first phosphorylation is catalyzed by PDK-1 on a conserved segment near the entrance to the active site referred to as the activation loop (Figure 1), an event that structures the active site for substrate binding and catalysis. The phosphorylation of the activation loop by PDK-1 triggers two tightly coupled phosphorylations at two conserved positions in the carboxyl terminus, the turn motif and hydrophobic motif (Figure 1). These latter phosphorylation events depend on mTORC2, but whether by direct phosphorylation or because mTORC2 structures or positions PKC for C-terminal phosphorylations (which are mediated by intramolecular autophosphorylation *in vitro*) remains to be resolved. These phosphorylations lock PKC in its mature and

catalytically competent conformation. It is this species of PKC that is activated by lipid hydrolysis and transduces signals.

PKC Translocation

Mature (i.e., phosphorylated) PKC is typically localized to the cytosol where it bounces on and off the membrane by diffusion-controlled mechanisms (although it is often scaffolded at specific locations, thus, increasing the local concentration for more effective signaling; see below). It is maintained in an inactive conformation because the pseudosubstrate sequence occupies the substrate-binding cavity. For conventional PKC isozymes, generation of Ca²⁺ and diacylglycerol target PKC to the membrane by binding the C2 and C1 domains and, thus, tethering the enzyme to membranes. The membrane-bound species adopts an active conformation by removal of the pseudosubstrate from the substrate-binding cavity, allowing substrate binding, phosphorylation, and downstream signaling. Finding a membrane-embedded ligand (diacylglycerol) by diffusion from the cytosol is a low-probability event, and, in the case of conventional PKCs, nature has chosen a clever mechanism to increase the efficiency of this. Binding of Ca²⁺ to the C2 domain essentially pretargets conventional PKC to the

Figure 2 Protein kinase C was visualized in cells by expression of a construct of protein kinase C fused to a naturally-fluorescent protein from the jellyfish *Aequorea victoria*, the green fluorescent protein (GFP). (a) Shows that protein kinase C is localized to the cytosol in unstimulated MDCK cells (diffuse fluorescence throughout the cell); (b) shows that protein kinase C translocates to the membrane (strong fluorescence intensity at cell periphery) following 1 min of treatment with the agonist UTP, which induces phospholipid hydrolysis and generation of the two second messengers for protein kinase C: Ca^{2+} and diacylglycerol. (c) Shows that protein kinase C has redistributed back to the cytosol 5 min after UTP treatment; second messenger levels have returned to resting levels. Images courtesy of Jon Violin.

membrane (primarily plasma membrane, where the C2 domain binds phosphatidylinositol-bis-phosphate (PIP_2)), where it can now initiate a much more effective search for its membrane-embedded ligand, diacylglycerol. As a consequence, conventional PKCs translocate to membranes approximately one order of magnitude faster than novel PKC isozymes, which do not have the advantage of pretargeting by a Ca^{2+} -responsive C2 domain. Nonetheless, novel isozymes are able to respond to diacylglycerol because their C1b domain is tuned to be an order-of-magnitude more responsive to diacylglycerol; these isozymes preferentially bind Golgi, which is unusually rich in diacylglycerol.

The advent of fluorescent methodologies has allowed imaging of PKC translocation and activity in real time in living cells (Figure 2). Notably, targeted reporters have allowed the visualization of kinase translocation, activity, and second messenger levels at precise intracellular locations, from specific membranes to protein scaffolds. In general, PKC translocation and activity mirror the generation of its second messengers. For example, histamine stimulation of HeLa cells results in oscillations in PKC substrate phosphorylation that are phase-locked with Ca^{2+} oscillations. Conventional PKC isozymes translocate rapidly to plasma membrane with kinetics mirroring Ca^{2+} elevation; diacylglycerol retains these isozymes at the plasma membrane and their activity here decays in concert with diacylglycerol. Novel isozymes translocate more slowly to Golgi membranes, where their activity is sustained because of sustained diacylglycerol at the Golgi.

PKC Scaffolds

Correct subcellular location is essential for normal signaling by PKC. An abundance of scaffold proteins that tether PKC near its substrates, activators, and regulatory proteins, such as phosphatases, has been described, most notably receptors for activated C kinases. The importance of correct subcellular location is perhaps best illustrated in the *Drosophila* visual cascade, where mutants lacking the PKC-binding scaffold, InaD, are defective in visual transduction because components of the signaling cascade are mislocalized.

PKC Downregulation

Prolonged activation of PKC by treatment of cells with phorbol esters results in degradation of PKC, a phenomenon referred to as downregulation. In fact, prolonged treatment of cells with phorbol esters is a commonly used approach to deplete cells of all except atypical PKCs (these are resistant to phorbol ester-dependent downregulation because they do not bind phorbol esters). The first step in downregulation is the dephosphorylation of the hydrophobic motif site by the recently discovered phosphatase PH-domain leucine-rich repeat protein phosphatase, an event that shunts PKC to a detergent-insoluble fraction where it is further dephosphorylated, ubiquitinated, and degraded via a proteosomal pathway. The molecular chaperone HSP70 protects PKC from downregulation by allowing rephosphorylation of the enzyme and sustaining its signaling lifetime.

PKC Signaling

PKC phosphorylates an abundance of substrates, including membrane proteins, cytoskeletal proteins, cytosolic proteins, and nuclear proteins. It plays key roles in diverse biological processes, many involving cell-survival pathways. Indeed, its role in cancer is becoming increasingly apparent. Not only are levels of specific isozymes frequently altered in cancer, but also driver mutations in several PKC isozymes have recently been identified in human tumors, underscoring the key role these enzymes play in maintaining cellular homeostasis.

Genetic deletion of specific isozymes results in subtle phenotypic differences, suggesting functional redundancy of the isozymes. It is interesting to note, however, that animals deficient in PKC isozymes are frequently deficient in adaptive responses. For example, mice lacking PKC ϵ have reduced anxiety and have reduced tolerance to alcohol. Mice lacking PKC γ have reduced pain perception and mice lacking PKC β II have reduced learning abilities and an impaired immune response. This theme carries over to the molecular level where many of the substrates of PKC are receptors which become desensitized following phosphorylation by PKC.

Isozyme-specific functions have been most clearly delineated for novel and atypical PKC isozymes. For example, PKC δ activation has been shown to play a role in apoptosis. PKC θ plays a key role in immune responses, and mice deficient in this isozyme have impaired T-cell signaling and interleukin 2 production. Defined functions have also been established for PKC ζ : this isozyme is required for maintenance of cell polarity and, in addition, regulates cell growth, DNA synthesis, and activation of the transcription factor, nuclear factor-kappa B (NFkB).

The amplitude of the PKC signal depends on (1) the cellular levels of PKC, which are controlled by phosphorylation and dephosphorylation, (2) the acute activity of PKC, which is controlled by second messengers, and (3) the subcellular localization of PKC, which is controlled not only by membrane interactions, but also by protein scaffolds. Each mechanism is precisely controlled. Dysregulation at any step results in pathophysiological states, notably cancer, where it is becoming

increasingly apparent that this family of isozymes plays key roles in controlling cell growth and survival.

Glossary

Heterogeneous acylation Nmt-catalyzed attachment of the following acyl chains having somewhat lower hydrophobicity than C14:0: tetradecenoate (C14:1^{Δ5}), tetradecadienoate (C14:2^{Δ5,8}), or laurate (C12:0). At present, this modification is only known to occur in retinal photoreceptor cells.

N-myristoylproteins This diverse group of covalently modified proteins use their acyl chain to promote a variety of readily reversible interactions with various cellular membranes or with other proteins. The stability of their interactions can be regulated by other modifications, including conformational changes that affect the presentation of the myristoyl moiety, posttranslational

acylation at other sites with other lipids, or charge–charge interactions mediated by protein side chain atoms.

N-myristoyltransferase (Nmt) An enzyme that catalyzes the linkage of myristate, via an amide bond, to the N-terminal glycine amine of cellular proteins. Catalysis occurs through the nucleophilic addition–elimination reaction. The acyl chain length specificity of the enzyme has been highly conserved during evolution, while its peptide substrate specificity has diverged among species. Nmt is a target for the development of drugs against fungal and other human pathogens.

Protein N-myristoylation The covalent attachment of myristate, a 14-carbon saturated fatty acid (C14:0), to the N-terminal glycine residue of eukaryotic proteins.

Protein N-myristoylation refers to the covalent attachment of myristic acid, a 14-carbon saturated fatty acid (C14:0), to the N-terminal glycine of proteins. Linkage occurs via an amide bond and takes place as proteins are being synthesized. N-myristoylproteins have varied intracellular destinations, and are involved in myriad cellular functions ranging from signal transduction to protein and vesicular trafficking. N-myristoylproteins are encountered in members of all kingdoms of the eukaryotic domain (Protist, Fungi, Plant, and Animal), but are not produced by members of Bacteria or Archaea. MyristoylCoA: protein N-myristoyltransferase (Nmt), E.C. 2.3.1.97, a member of the GCN5 acetyltransferase (GNAT) superfamily, is responsible for catalyzing the transfer of myristate from myristoylCoA to proteins. While the acylCoA substrate specificity of Nmt has been highly conserved during evolution, its peptide substrate specificities have diverged among eukaryotes.

Protein N-myristoylation has relevance to a number of diseases. Genetic and pharmacologic studies have shown that Nmt activity is essential for the survival of a number of fungi that cause systemic infections in immunocompromised humans. These organisms include *Candida albicans* and *Cryptococcus neoformans*. Protein N-myristoylation is also critical to the life cycle of viruses, such as human immunodeficiency virus-1. Nmt levels are elevated in human gastrointestinal tract malignancies. Other pathogens, including *Plasmodium falciparum*, the parasite that causes malaria, have NmTs. Therefore, understanding the contributions of myristate to protein function, elucidating the structural basis for the divergent protein substrate specificities of orthologous NmTs, characterizing the myristoyl transfer reaction, and identifying biologically active, species-selective Nmt inhibitors may provide new therapeutic strategies and agents.

N-Myristoylproteins

Function of N-Myristoylation

Myristate exposed on the surface of a protein increases its lipophilicity, allowing transient, low-affinity interactions with cellular membranes or other proteins. This feature makes N-myristoylation an attractive choice for molecules involved in a variety of signaling cascades, such as protein kinases, kinase substrates, and protein phosphatases.

Myristate is not sufficiently hydrophobic to allow stable anchorage to cellular membranes. Therefore, most N-myristoylproteins utilize an additional mode of attachment. One supplementary membrane tether is provided by the reversible posttranslational covalent attachment of palmitate, a 16-carbon saturated fatty acid (C16:0), to cysteine (S-palmitoylation). Alpha subunits of heterotrimeric G proteins provide examples of this type of dual acylation. Other N-myristoylproteins, such as the protein tyrosine kinase Src, use positively charged exposed residues to interact electrostatically with negatively charged groups in membrane lipids. Some N-myristoylproteins regulate their association with membranes through reversible exposure of their myristoyl moiety. Recoverin, a retinal photoreceptor protein involved in light adaptation, illustrates this ‘myristoyl-conformational switch’: its myristoyl group is unfurled when the protein binds calcium; in the absence of calcium, the acyl chain is encased in a hydrophobic pocket.

Heterogeneous acylation is another device used by N-myristoylproteins to achieve regulated membrane association. Heterogeneous acylation refers to Nmt-catalyzed linkage of tetradecanoate (C14:0), tetradecenoate (C14:1^{Δ5}), tetradecadienoate (C14:2^{Δ5,8}), or laurate (C12:0) to a substrate protein. At present, this phenomenon has only been described in

retinal photoreceptor cells. Augmented production of these acylCoAs, and/or increased access of Nmt to these species, is among the mechanisms that have been invoked to account for the observed cell-lineage-specificity of heterogeneous acylation.

Examples of heterogeneously acylated proteins include recoverin, the α -subunit of the G protein transducin (Gtz), guanylyl cyclase activating protein, and the catalytic subunit of cyclic adenosine monophosphate (cAMP)-dependent protein kinase. Lauric acid and C14 fatty acids, containing a *cis* double bond between C5–C6 (C14:1^{Δ5}) or C5–C6 and C8–C9 (C14:2^{Δ5,8}), have reduced hydrophobicity compared to C14:0. A less hydrophobic acyl chain may be required for these proteins to properly operate in photoreceptor cells, either because of their extraordinarily high concentrations of membranes, and/or because the proteins require short-lived anchorage to membranes to rapidly transduce responses in visual signaling pathways.

Substrate Selection

Most proteins targeted for cotranslational N-myristoylation have an N-terminal consensus sequence of Met–Gly–X–X–X–Ser/Thr. The initiator methionine must first be removed from the nascent protein by another enzyme, methionylaminopeptidase, to expose the acceptor glycine. However, this consensus sequence is too general to allow definitive identification of Nmt substrates. Furthermore, in at least one case involving the pro-apoptotic protein BID, an internal myristoylation site is exposed after posttranslational proteolytic cleavage. **Figure 1** provides a more detailed recognition consensus sequence that has been developed from an analysis of known N-myristoylproteins, as well as currently available X-ray crystal structures of Nmt.

There are a number of ways to establish that a protein is N-myristoylated, including metabolic labeling with tritiated or iodinated myristate, mass spectrometric analysis of the purified protein, or *in vitro* Nmt assays that contain the purified acyltransferase, myristoylCoA, and a peptide encompassing the N-terminal 8–15 residues of the candidate protein substrate. A current listing of experimentally confirmed as well as candidate N-myristoylproteins can be found at the website address listed in the Relevant Website section.

Escherichia coli containing a dual plasmid expression system has also been used widely to determine whether a protein is an Nmt substrate, and to study the functional significance of its myristoyl group. The system takes advantage of the fact that this bacterium is able to generate myristoylCoA but does not

have any endogenous Nmt activity. The eukaryotic protein modification is recapitulated in this prokaryote by using one plasmid with an inducible promoter to direct expression of an Nmt, and another plasmid, containing a different inducible promoter, to express a candidate Nmt substrate. Production of Nmt is initiated first. Synthesis of the protein substrate is then turned on to allow for its cotranslational acylation. Incorporation of myristate can be verified by metabolic labeling or by mass spectrometry. The properties of the N-myristoylated protein can be compared and contrasted to that of the nonmyristoylated isoform produced in *E. coli* lacking the Nmt expression vector.

N-Myristoyltransferase

Thus far, a total of 68 known and postulated Nmts have been identified from 63 species. Four mammalian genomes (*Homo sapiens*, *Mus musculus*, *Rattus norvegicus*, and *Bos Taurus*), plus a plant genome (the mustard weed, *Arabidopsis thaliana*), contain two Nmt genes (designated type I and type II). Type I Nmts show a high degree of conservation among one another, as do the type II acyltransferases. Type I and II enzymes diverge most prominently at their N termini. These N-terminal domains are not required for catalytic activity *in vitro* but may help direct the acyltransferase to different intracellular sites. For example, the N terminus of type I human Nmt appears to be involved in its targeting to the ribosome.

Reaction Mechanism

The N-myristoyltransferase reaction mechanism has been characterized using the *Saccharomyces cerevisiae* enzyme as a model. *S. cerevisiae* Nmt contains 455 amino acids, is monomeric, and has no known cofactor requirements. Steady-state kinetics, isothermal titration calorimetrics, and X-ray crystallographic studies indicate that the enzyme has an ordered Bi–Bi reaction mechanism. The apo-Nmt first binds myristoylCoA to form a Nmt:myristoylCoA binary complex. MyristoylCoA binding allows subsequent binding of a nascent protein substrate to generate a Nmt:myristoylCoA:peptide ternary complex. Following the chemical transformation step (conversion of the enzyme:substrate complex to the enzyme:product complex), CoA and then myristoylpeptide are released. Pre-steady-state kinetic studies indicate that the rate-determining step occurs after the chemical transformation, most likely involving release of myristoylpeptide.

Catalysis occurs through a classic nucleophilic addition–elimination reaction where the nucleophilic N-terminal Gly

Figure 1 Consensus sequence for recognition of protein substrates by N-myristoyltransferase (Nmt) (*side chain volume compensation allowed; fungal Nmts allow hydrophobic residues; § some fungal Nmts prefer small residues; and || often S or T). Figure based on Maurer-Stroh S, Eisenhaber B, and Eisenhaber F (2002) N-terminal N-myristoylation of proteins: Refinement of the sequence motif and its taxon-specific differences. *Journal of Molecular Biology* 317: 523–540, 541–557.

amine of the peptide substrate attacks the polarized thioester carbonyl of myristoylCoA. Several elements in the enzyme's active site facilitate this reaction. An oxyanion hole, formed by the backbone amides of two conserved residues, Phe170 and Leu171, polarizes the reactive carbonyl of myristoylCoA. The C-terminal carboxylate (Leu455 in the yeast enzyme) functions as a catalytic base to deprotonate the Gly1 ammonium to a nucleophilic amine. The amine rotates 180° along Ψ to reduce its distance from the thioester carbonyl of myristoylCoA. H-bonding interactions between the Gly1 amine, Asn169, and Thr205 help direct the reaction trajectory, and facilitate nucleophilic attack of the polarized carbonyl. The oxyanion hole, together with the H-bonding network formed by Asn169 and Thr205, stabilizes the developing tetrahedral intermediate. With subsequent collapse of the intermediate, CoA is extruded. The Gly1 amine is deprotonated, while the thiolate-leaving group of CoA is reprotonated.

Three-Dimensional Structure of Nmt: Insights about Substrate Recognition/Acquisition and Release

Presently, three X-ray crystal structures of *S. cerevisiae* Nmt have been reported: a binary complex containing bound myristoylCoA (Protein Data Bank (PDF) accession 1IIC), plus two ternary complexes – one with a peptide substrate and S-(2-oxo)pentadecylCoA (a nonhydrolyzable myristoylCoA analog containing a methylene interposed between the sulfur of CoA and the carbonyl of myristate; PDF 1IID) and the other with S-(2-oxo)pentadecylCoA and a dipeptide inhibitor (PDB, 2NMT). In addition, three structures of *C. albicans* Nmt are available: the apo-enzyme (PDB, 1NMT), the enzyme with bound myristoylCoA and peptidic inhibitor (PDB, 1IYK), and the enzyme with a bound benzofuran inhibitor (PDB, 1IYL).

The Nmt fold consists of a large saddle-shaped β -sheet with several α -helices located on either side (Figure 2). There is pseudo-twofold symmetry. The N-terminal half forms the myristoylCoA-binding site, while the C-terminal half contributes to peptide recognition. The N terminus is disordered.

Binding of myristoylCoA induces two important conformational changes. A 3_{10} helix (A' in Figure 2) is formed from part of the disordered N terminus, to complete the myristoylCoA binding site. There is also a change in the conformation of a loop connecting helix A and strand b (Ab loop), thereby opening a lid overlying the peptide binding site. The pantetheine group of CoA forms a key component of the peptide recognition site. Together, these observations indicate why myristoylCoA binding is a prerequisite for subsequent acquisition of a nascent protein substrate.

MyristoylCoA is bound to Nmt in a conformation that resembles a question mark (Figure 2). Nmt uses residues that produce bends at C1 and C6 of the bound myristoyl chain, as well as the floor of its acylCoA-binding pocket, to measure and properly position myristoylCoA. Available X-ray structures indicate that the two additional methylenes present in palmitoylCoA cannot be accommodated by the enzyme without adversely affecting positioning of its thioester carbonyl within the oxyanion hole.

The X-ray structures suggest that the extent of ordering of the Ab loop may correlate with the overall catalytic efficiency of different Nmt peptide substrates, and that the rate-limiting step

Figure 2 Ribbon diagram of *S. cerevisiae* Nmt. The enzyme is shown with a S-(2-oxo)pentadecylCoA, a nonhydrolyzable myristoylCoA analog and competitive inhibitor, and an octapeptide substrate (GlyLeuTyrAlaSerLysLeuAla) derived from the N terminus of ADP ribosylation factor 2 (Arf2). Binding of the myristoylCoA induces ordering of a 3_{10} helix (A'), a change in the conformation of the Ab loop, and completion of the peptide binding site. The C-terminal carboxylate (Leu455) functions as a catalytic base to deprotonate the Gly1 ammonium to a nucleophilic amine.

in the Nmt reaction is an isomerization involving reversal of the conformational changes that take place when myristoylCoA is bound. In other words, it indicates disordering of the 3_{10} A' helix and opening the lid formed by the Ab loop.

Therapeutics

Alignments of known NmTs disclose that their N-terminal halves are more conserved than their C-terminal halves. This finding is consistent with their shared specificity for myristoylCoA, and with the divergent nature of their protein substrate specificities. Exploiting the differences in peptide recognition among NmTs may be key to developing species-specific inhibitors. This divergence, and the fact that genetic experiments have established that pathogenic fungi such as *C. albicans* and *C. neoformans* require Nmt for their survival, makes N-myristoyltransferase an attractive target for developing new classes of fungicidal agents. The need for such agents is great, given the limited number of existing drugs that effectively kill these organisms, and the increasing resistance being encountered to these available compounds.

Several classes of Nmt-targeted antifungal agents have been identified to date. Peptidomimetic inhibitors have been produced starting from an octapeptide substrate representing the N terminus of *S. cerevisiae* adenosine diphosphate (ADP) ribosylation factor 2 (Arf2) (involved in vesicular trafficking). Benzofuran inhibitors have emerged from high-throughput screens of chemical libraries. These benzofurans have several advantages over the Arf-derived compounds – smaller size,

increased bioavailability, and resistance to degradation. Crystallographic studies of *C. albicans* Nmt revealed that one of the lead benzofurans was positioned in a hydrophobic pocket located within the enzyme's peptide substrate-binding site. Using this structural information, a more biologically active derivative, substituted with difluorophenoxy- and pyridyl-terminated side chains, was created that inhibits fungal growth in a rat model of systemic Candidiasis. Further screens for compounds that display specificity for fungal compared to human NmTs are likely to yield additional classes of fungicidal compounds in the future.

Glossary

DHHC–CRD motif A protein sequence motif that is associated with the class of palmitoyltransferase that carries out the S-palmitoylation of proteins.

Palmitoylation The process by which proteins become covalently modified by long-chain fatty acids related to palmitic acid.

Palmitoylthioesterase An enzyme that cleaves palmitate from S-palmitoylated proteins.

Protein acyltransferase (PAT) An enzyme that carries out the palmitoylation of proteins.

Palmitoylation is the covalent modification of proteins with 16 carbon acyl chains related to palmitic acid. Protein palmitoylation was first described in the 1970s and is now recognized as a major form of posttranslational modification in all eukaryotes, with a few examples in prokaryotes as well. In many cases, palmitoylation is a reversible modification, suggesting that the cell uses it to regulate protein function. This article focuses on the enzymology and functional significance of protein palmitoylation.

Covalent Modification of Proteins with Palmitoyl Groups

Palmitoylation refers to a family of protein modifications involving palmitic acid (Figure 1). The most common forms of palmitoylation are S-palmitoylation and N-palmitoylation. S-palmitoylation occurs on cysteine residues and involves a thioester linkage. In the cases where it has been investigated, S-palmitoylation is a reversible modification. Examples include receptors, signaling proteins, and scaffold proteins. N-palmitoylation reactions occur on the amino terminus or on the epsilon amino group of lysine. Reports of esterification of palmitate with serine and threonine residues (O-palmitoylation) have appeared for myelin proteolipids; however, other studies conclude that myelin proteolipids are S-palmitoylated. Protein palmitoylation is generally detected by labeling cells or cell extracts with [³H]-palmitate. Identification of the covalently linked lipid is done by chemical or enzymatic cleavage followed by high-performance liquid chromatography (HPLC) analysis. In most cases, palmitate is found, but in some cases, unsaturated forms of palmitate are also detected. An estimate of the total extent of protein palmitoylation in the cell is difficult to obtain because of the rapid reversibility of palmitoylation and the chemical lability of thioesters. Proteomic methods that account for posttranslational modifications have begun, but application to lipid modifications needs further development. However, based on the growing list of palmitoylated proteins reported, it is clear that palmitoylation is a significant posttranslational modification.

Palmitoyltransferases

There has been a debate concerning whether palmitoylation is spontaneous or enzyme mediated. The thiol of cysteine is capable of serving as a nucleophile in a spontaneous S-acylation reaction using palmitoyl-CoA as the acyl donor. However, it is difficult to know whether spontaneous palmitoylation occurs *in vivo*. It is more likely that protein acyltransferase(s) (PATs) are responsible for palmitoylation under physiological conditions. In fact, PAT activities that cofractionate with the plasma membrane and endomembranes have been reported, suggesting that there is either ubiquitous expression of a single PAT or multiple PATs with distinct subcellular distributions. The recent discovery of protein PATs in model organisms has begun to shed light on this question.

Plasma membrane localization of Ras requires palmitoylation of a conserved cysteine located close to the C terminus. Palmitoylation is associated with the translocation of Ras from the endoplasmic reticulum (ER) to the plasma membrane where it functions in signaling. A genetic screen was carried out in yeast to identify mutants affecting Ras palmitoylation. Mutations in two genes, *ERF2* and *ERF4*, were identified. Lobo and co-workers found Erf2p and Erf4p form a complex that together carries out the enzymatic palmitoylation of Ras. The new enzyme is called Ras PAT. Erf2p has a conserved domain referred to as a DHHC–CRD motif (Pfam designation zfDHHC). Another yeast DHHC–CRD protein, Akr1p, has been shown to be the PAT for yeast casein kinase, Yck2p. Thus, Erf2p/Erf4p and Akr1p are founding members of a new class of S-PATs. The DHHC–CRD motif is found in six other yeast proteins, 23 human proteins, and all other organisms examined.

Not all palmitoylated proteins are intracellular. The *Drosophila* secretes signaling molecules, Hedgehog and Wnt, which are also palmitoylated. Again, genetic screens led to a candidate PAT. The gene goes by the names *skinny hedgehog* (*ski*), *sightless* (*sit*), or *rasp* depending on the group that isolated the mutation. A clue to the function came from a short region of sequence similarity with O-acyltransferases. Members of this family transfer fatty acids onto hydroxyl groups of nonproteinaceous targets. Mutation of residues in the conserved domain of *ski/sit/rasp* results in loss of Hedgehog palmitoylation and signaling.

S-palmitoylation

Examples: G proteins and G-protein-coupled receptors, Ras, Src, PSD-95

N-palmitoylation

Examples: Hedgehog, G_s , adenylate cyclase (*Bordetella pertussis*)

O-palmitoylation

Example: myelin proteolipids

Figure 1 The three major classes of covalent attachment of palmitate in proteins. Representative examples of each type are listed.

Biochemical studies are still needed to confirm that *ski/sit/rasp* is a PAT and to elucidate the mechanism.

The Wnt proteins are cysteine-rich secreted glycoproteins that have recently been shown to be palmitoylated on conserved cysteine. The modification could be removed by an acylprotein thioesterase (APT1) consistent with it being a thioester. Sequence alignment of Wnt family members reveals that this is the first cysteine residue in the sequence that is conserved in all family members. Thus, palmitoylation is likely to be found on all Wnt signaling proteins. Enzymatic depalmitoylation of purified Wnt3a protein results in the loss of its ability to stabilize β -catenin in mouse L cells, a measure of the Wnt signaling pathway. *porcupine* (*por*) is a segment polarity gene in *Drosophila* that is required for processing and secretion of Wingless (Wg). In *por* mutants, Wg is confined to cells where it is synthesized. Like *skinny hedgehog* (*ski*)/*sightless* (*sit*)/*rasp*, porcupine shares sequence homology with O-acyltransferases making it an excellent candidate for the Wnt PAT.

Palmitoylthioesterases

Given the reversible nature of protein palmitoylation, thioesterases are predicted to play an important regulatory role. However, the first protein thioesterases identified, PPT1 and PPT2, are apparently involved in protein turnover. PPT1 found in lysosomes and mutations, which reduce or eliminate its expression, causes a severe neurodegenerative disorder, infantile neuronal ceroid lipofuscinosis (INCL). INCL is formally classified as a lysosomal-storage disorder. The neurological phenotype arising from a deficiency of PPT thioesterases is likely to be caused by the accumulation of palmitoyl peptides or palmitoylcysteine.

A cytosolic palmitoyl protein thioesterase, APT1, was discovered in rat liver extracts. APT1 was originally described as a lysophospholipase, but Duncan and Gilman showed that APT1 cleaves thioesters in acyl-CoAs and acylproteins, as well as oxyesters in lysolipids. In fact, APT1 exhibits a strong substrate preference for acylproteins over lipid substrates consistent with a role for APT1 as a regulator of protein thioacylation and not as a regulator of lipid metabolism. A number of substrates have been proposed for APT1, including G_{α} -subunits, Ras, and eNOS. APT1 orthologs have been identified in a large number of species, ranging from yeast to humans.

Palmitoylation and Protein Function

The functional significance of reversible palmitoylation depends on the protein under consideration. For peripheral membrane/cytosolic proteins, lipid addition can be the primary determinant of membrane recruitment. It can also specify a particular membrane or microdomain of a membrane. A theme that has emerged from many studies is that palmitoylation operates along with other lipid modifications or membrane association sequences. Ras proteins are a case in point. Farnesylation of the C-terminal *CaaX* box targets H-Ras and N-Ras to the cytosolic surface of the ER membrane where it is further processed by a *CaaX* box protease and methyltransferase. Plasma membrane localization of H-Ras requires palmitoylation by the Erf2p/Erf4p Ras PAT. Once at the plasma membrane, H-Ras reversibly associates with microdomains believed to be involved in signaling. There is intense interest in defining the nature of this microdomain and the role of palmitoylation in Ras signaling.

Reversible palmitoylation also influences the subcellular trafficking of integral membrane proteins. For example, receptor endocytosis and recycling is often controlled by palmitoylation status. In virus-infected cells, palmitoylation directs Env proteins to lipid rafts where viral assembly occurs. In addition to surface expression and stability, palmitoylation has been proposed to play a role in signaling of some receptors. Palmitoylation can effect signaling by altering effector binding. For example, mutations in the palmitoylation site on the cytoplasmic tail of the β -adrenergic receptor leads to uncoupling of the receptor, its cognate G protein.

Palmitoylation also plays a role in vesicle trafficking and membrane fusion. Palmitoyl-CoA is required for efficient vesicle fusion in cell free assays. It is generally believed that palmitoylation of a specific protein or proteins accounts for

this requirement. A possible candidate has emerged from the study of vacuole inheritance in yeast. Vac8p is a myristoylated and palmitoylated peripheral membrane protein that is required for vacuole inheritance. Palmitoylation, but not myristoylation, is required for Vac8p function. Palmitoylation of Vac8p may be involved in the interaction of Vac8p with vacuole-specific N-ethylmaleimide sensitive factor attachment protein receptor (SNARE) complexes.

Not all palmitoylation is involved with membrane-mediated processes. Mitochondrial methylmalonyl semialdehyde dehydrogenase is covalently modified by palmitate on an active site cysteine residue. Insertion of [125 I]-labeled analog of myristoyl-CoA at this site results in enzyme inhibition. This observation, together with other results that palmitoyl-CoA inhibits the activity of several mitochondrial enzymes, suggests a regulatory role of S-acylation in metabolism.

Palmitoylation Inhibitors

The role of palmitoylation in cellular processes has been investigated using inhibitors such as 2-bromo or 2-fluoropalmitate, cerulenin, and tunicamycin. Each inhibits protein palmitoylation, but their mechanisms of action may differ. Cerulenin inhibits fatty acid synthase, but analogs with selectivity toward PATs are being developed and tested. Tunicamycin is a fatty acyl-CoA analog and has been found to reduce protein palmitoylation without significantly affecting palmitoyl-CoA levels. In some cases, 2-fluoropalmitate has been shown to decrease uptake of [3 H]palmitate and thereby lower the levels of labeled palmitoyl-CoA levels and apparent protein palmitoylation. The recent identification of palmitoyltransferases should allow a more detailed characterization of these inhibitors and the development of new inhibitors with specificity toward the different classes of palmitoylated proteins.

Concluding Remarks

Protein palmitoylation has emerged as an important posttranslational modification used by cells to organize the subcellular distribution of proteins on membranes. The study of protein palmitoylation has entered a new phase with the identification of PATs in yeast and *Drosophila*. As the tools develop, the role

of protein palmitoylation, in the cellular physiology, should come into better focus. PATs may be excellent targets for the design of drugs that alter the subcellular distribution of receptors and signaling molecules.

Glossary

Classic ‘protein tyrosine phosphatase’ (PTP) These enzymes are specific for phosphotyrosine substrates.

Dual-specific PTPs (DS-PTPs) In addition to having the ability to dephosphorylate phosphotyrosine substrates *in vitro*, DS-PTPs have been shown to utilize phosphoserine/threonine, RNA, inositol lipids, or phospho-glucans as their physiological substrates.

Kinase Enzymes that work opposite of phosphatases by catalyzing the addition of phosphate group to a target substrate.

Phosphatases Catalyze the removal of a phosphate group from a target substrate.

Receptor-like PTP (RPTP) PTPs possessing a transmembrane domain and one or two classic, phosphotyrosine-specific PTP domain.

Introduction

The process of reversible phosphorylation is perhaps the cell's most prevalent means of regulation at the molecular level. It has been estimated that up to 30% of all cellular proteins are phosphorylated, and phosphorylation has been shown to play a crucial regulatory role in such diverse cellular events as metabolism, growth and differentiation, vesicular transport, and gene transcription. Phosphorylation and dephosphorylation are carried out by kinases and phosphatases, respectively. There are currently predicted to be 518 kinases and ~125 phosphatases encoded in the human genome, further underscoring the overall importance of phosphorylation in molecular regulation. Phosphatases are generally divided into two main families based on their catalytic mechanism and substrate specificity: the protein phosphatases (PPs), which exclusively desphosphorylate serine and threonine residues, and the protein tyrosine phosphatases (PTPs), which can dephosphorylate tyrosine residues, and are the focus of this article. PTPs can be further classified into subfamilies based on (1) subcellular location (receptor vs. intracellular), (2) substrate preference, and (3) three-dimensional topology. In this article, we describe the different subfamilies of PTPs and their conserved catalytic mechanism. In addition, we briefly discuss human diseases that result from disrupted PTP signaling, and discuss the pursuit of PTPs as drug targets.

Catalytic Mechanism of PTPs

PTPs, regardless of subfamily, are predicted to use similar mechanisms for catalyzing the removal of a phosphate group. All PTPs possess a catalytic domain that contains the active-site signature motif cysteine- X_5 -arginine (CX_5R ; X = any amino acid), which constitutes the phosphate-binding pocket, or ‘P-loop’. The dephosphorylation reaction is initiated when the thiol nucleophile of the active-site cysteine attacks the phosphate group on the substrate molecule, forming a cysteinyl-phosphate intermediate (Figure 1). A conserved aspartic acid, usually residing outside of the P-loop, then acts as a general acid to aid in the ejection of the substrate molecule. In the second step of the

reaction, the phosphoenzyme intermediate is hydrolyzed by a water molecule that has been activated by the aspartate, thereby releasing free phosphate and regenerating the active enzyme.

Classification of PTPs

Intracellular PTPs

PTPs

PTPs can be classified as receptor-like (RPTPs) or intracellular based on their location within a cell, whereas all RPTPs to date exhibit specificity toward phosphotyrosine substrates (referred to as ‘classic’ PTPs); intracellular PTPs can be classic or dual-specific (DS-PTPs), having the ability to dephosphorylate serine/threonine, RNA, or inositol lipids in addition to pTyr (Figure 2). The major distinguishing factor between classic and DS-PTPs appears to be the depth of the substrate-binding pocket, with DS-PTPs having a shallower landscape less conducive to the binding of the long side chain of tyrosine. A series of structural studies over the past decade have revealed that all PTPs possess one of three distinct topologies (Figure 3). This first and largest topological family, referred to simply as PTPs, includes all of the RPTPs, classic PTPs such as PTP1B and the *Yersinia* PTP, and DS-PTPs such as vaccinia VH1-related (VHR) and phosphatase and tensin homolog (PTEN), among others (Figure 2).

CDC25 family

The CDC25 family is a set of DS-PTPs involved in the regulation of the cell cycle. Each enzyme of this family is highly specific for a particular serine or threonine residue on a cyclin-dependant kinase/cyclin complex. Although presence of the signature CX_5R motif suggests a common catalytic mechanism, the PTP domains of these enzymes share little sequence homology with other PTPs (Figure 3).

Low-molecular-weight PTPs

The third family of topologically distinct CX_5R phosphatases is the low-molecular-weight PTPs (LMW-PTPs). Conservation of the catalytic cysteine, arginine, and aspartic acid residues strongly suggests that these enzymes also utilize a similar

Figure 1 Catalytic mechanism of protein tyrosine phosphatases. Step 1: a thiolate anion of the active-site cysteine performs a nucleophilic attack on the phosphate of phosphoryl-tyrosyl substrates, resulting in the formation of a phospho-enzyme intermediate. An aspartic acid, acting as a general acid, donates a proton to the phosphate group, ejecting the tyrosine side chain. Hydrogen bonds between phosphate oxygen atoms and nitrogen atoms of the arginine guanido group promote phosphate binding and stabilize the transition state. Step 2: acting as a general base, aspartate activates a water molecule for a nucleophilic attack on the phosphorous atom. The phosphorous-sulfur bond is hydrolyzed, thus, regenerating the native enzyme. Reproduced from Denu JM, Stuckey JA, Saper MA, and Dixon JE (1996) Form and function in protein dephosphorylation. *Cell* 87: 361–364.

catalytic mechanism. As with the CDC25 family, however, LMW-PTPs show no homology with other PTPs, and a lack of any other domains outside of their small (~150 amino acids) PTP domain provides few clues to their *in vivo* function. All LMW-PTPs examined to date have been specific for tyrosine-phosphorylated substrates.

Receptor-Like PTPs

RPTPs possess an extracellular receptor-like domain, a single transmembrane domain, and one or two intracellular classic tyrosine-specific PTP domains. Where two PTP domains exist, the membrane proximal domain accounts for the majority of catalytic activity. Based on their active-site homology and common features of their extracellular domains, RPTPs can be further subdivided into eight subtypes: R1/R6, R2A, R2B, R3, R4, R5, R7, and R8 (Figure 2). The CD45 family (R1/R6) is expressed on nucleated hematopoietic cells and is thought to be involved in the positive regulation of antigen receptor signaling via dephosphorylation of the Src family kinases. RPTPs ρ , μ , κ , and λ (R2A) are marked by an extracellular meprin-A5 antigen-PTP μ (MAM) and intracellular cadherin-like domains. They also possess extracellular fibronectin type III-like repeats and an immunoglobulin-like domain on their extracellular region that are involved in cell adhesion. The leukocyte common antigen-related (LAR)-like PTPs (R2B) are primarily expressed in neuronal cells where they are thought to play an important role in neuronal development. They are marked by tandem repeats of immunoglobulin-like and fibronectin type III like domains resembling neuronal adhesion molecules. Members of the R3 subfamily, for example, the mammalian OST-PTP (OST, osteotesticular), possess multiple fibronectin type III repeats resembling cell-adhesion molecules such as collagen type VII, fibronectin, and tenascin. PTP α and PTP ϵ (members of R4) are marked by their relatively small,

highly glycosylated extracellular domains. PTP γ and PTP ζ represent the R5 subfamily, which have a carbonic anhydrase-like domain. RPTPs possessing a meprin domain in addition to immunoglobulin-like and fibronectin type III-like repeats comprise R6. Members of the R7 subfamily possess no additional extra- or intracellular domains, and the more evolutionarily distant R8 family members are predicted to be catalytically inactive.

PTPs and Human Disease

Involvement of PTPs in Mammalian Biology and Disease

At least 18 human protein tyrosine kinases (PTKs) have been shown to behave as onco-proteins when inappropriately activated by mutation. Given this, it was expected that PTPs, which can terminate tyrosine kinase signaling, might be found as genes frequently mutated in cancers. This has generally not proved to be the case. However, links between specific PTPs and human genetic diseases have been, and are continuing to be, established. In addition, numerous studies involving mice with targeted disruptions of individual PTP genes have provided *in vivo* evidence for the involvement of individual PTPs in specific biological processes. Abnormal PTP function has been implicated in a wide array of pathological conditions including diabetes, obesity, cancer, immune disease, neurodegeneration, and vascular disease. In this section, links between PTPs and human disease are briefly discussed. Studies of three PTPs that play essential roles in mammalian physiology are offered as examples. In addition, a summary of the results of PTP gene disruption experiments in mice is provided (Table 1). Finally, the development of PTP inhibitors for use as therapeutics and research tools is discussed.

PTP-1B

A number of studies over the last 5 years have indicated that PTP-1B plays a specific role in downregulating both insulin and leptin receptor signaling in mice. Studies from the laboratories of both Kennedy and Kahn have demonstrated that mice lacking PTP-1B are resistant to diabetes and diet-induced obesity, while displaying no other apparent physiological defects. Enhanced insulin sensitivity in PTP-1B-deficient mice likely results from hyperphosphorylation of the insulin receptor, as these mice display enhanced autophosphorylation of this protein in liver and muscle tissues. PTP-1B has been shown to associate with the insulin receptor PTK *in vivo* and both the insulin receptor and insulin receptor substrate 1 (IRS1) have been implicated as substrates for PTP-1B. Taken together, these data indicate a critical role for PTP-1B in turning off insulin signaling in sensitive mammalian tissues. The apparent *in vivo* specificity of PTP-1B function came as a surprise given the many other cellular processes in which this enzyme was thought to be involved. A number of pharmaceutical companies are attempting to generate specific inhibitors of PTP-1B for use as drugs to treat diabetes and obesity.

CD45

CD45 is an RPTP highly expressed in all nucleated hematopoietic cells. The extracellular portion CD45 contains fibronectin-like repeat sequences (Figure 2), is heavily glycosylated and

Figure 2 Schematic illustration of representative members of the PTP superfamily.

is involved in the homodimerization of the molecule. Ligands for the extracellular domain of CD45 have not been identified, but this segment of the protein is important for the regulation of phosphatase activity. The cytoplasmic portion of CD45 contains two PTP domains; however, only the membrane proximal PTP domain is catalytically active and required for CD45 function. Homodimerization of CD45 is believed to maintain the phosphatase domain in a low-activity state. CD45 mutations in either humans or mice result in a severe-combined immune deficient (SCID) phenotype, in which both B and T cells are affected (Table 1). Consistent with the SCID phenotype, studies in CD45-deficient mice have indicated a

role for this PTP as a critical positive regulator of immunoreceptor signaling in both B and T cells. In T cells, binding of an antigen to the extracellular portion of the T-cell receptor (TCR) results in the assembly of a cytoplasmic complex of TCR-associated-signaling proteins. The PTKs Lck and Fyn phosphorylate a number of components of the assembled TCR-signaling complex, leading to the recruitment and activation of the ZAP-70 PTK. Activated ZAP-70 participates in the transmission of stimulatory signals to downstream pathway components, ultimately leading to T-cell activation. The kinase activities of Lck and Fyn are negatively regulated by tyrosine phosphorylation on specific residues. By dephosphorylating these key inhibitory

Figure 3 Crystal structures and topologies of representative members of each of the three topologically distinct PTP subfamilies. The amino (N) and carboxyl (C) termini of the proteins are indicated. Circles represent α -helices; triangles represent β -strands. The location of the P-loop possessing the signature CX₅R motif is highlighted in green.

Table 1 Summary of PTP gene disruption experiments in mice

PTP	Mouse gene disruption phenotype and references
CD45	Severe-combined immunodeficiency (Byth et al., 1996; Kishihara et al., 1993; Mee et al., 1999)
CD148	Embryonic lethal (day 11.5); extensive vascular defects (Takahashi et al., 2003)
Cdc25b	Female sterility due to permanent meiotic arrest of oocytes (Lincoln et al., 2002)
Cdc25c	No phenotypic defects identified (Chen et al., 2001)
HePTP	Enhanced ERK activation in lymphocytes, but no physiological defects identified (Gronda et al., 2001)
Laforin	Neurodegeneration and Lafora body accumulation; ataxia, epilepsy, and impaired behavioral responses (Ganesh et al., 2002)
LAR	Decreased basal forebrain cholinergic neuron size and hippocampal cholinergic innervation; delayed regenerative neurite outgrowth following nerve injury; impaired mammary gland development; abnormal glucose homeostasis (Ren et al., 1998; Schaapveld et al., 1997; Van der Zee et al., 2003; Van Lieshout et al., 2001; Xie et al., 2001; Yeo et al., 1997)
PTP-1B	Enhanced sensitivity to insulin, leptin, and growth hormone; obesity resistance (Cheng et al., 2002; Elchebly et al., 1999a; Gu et al., 2003; Klamman et al., 2000; Zabolotny et al., 2002)
PTP α	No gross phenotypic defects; reduced activation of Src and Fyn kinases; altered integrin signaling and cell migration (Ponniah et al., 1999; Su et al., 1999; Zeng et al., 2003; Zheng and Shalloway, 2001)
PTP β	No phenotypic defects identified (Harroch et al., 2000)
PTP δ	Impaired learning; altered hippocampal long-term potentiation (Uetani et al., 2000)
PTP ϵ	No gross phenotypic defects; abnormal macrophage responsiveness; hypomyelination of sciatic nerve neurons; abnormal voltage-gated potassium channel function (Peretz et al., 2000; Sully et al., 2001)
PTP σ	Neonatal or early lethality; developmental defects in neuronal and neuroendocrine cell lineages (Batt et al., 2002; Batt et al., 2003; Elchebly et al., 1999b; McLean et al., 2002; Meathrel et al., 2002; Wallace et al., 1999)
SHP-1	Early lethality (<12 weeks); severe hematopoietic dysregulation and autoimmunity (Kamata et al., 2003; Kozlowski et al., 1993; Shultz et al., 1993; Tsui et al., 1993)
SHP-2	Embryonic lethality (day 10.5) with gastrulation defects; enhanced MAP kinase activation (Arrandale et al., 1996; Saxton et al., 1997)
TC-PTP	Early lethality (<5 weeks); defective bone marrow function; impaired B and T cell function (Dupuis et al., 2003; Galic et al., 2003; Ibarra-Sanchez et al., 2001; You-Ten et al., 1997)

tyrosines, CD45 acts to prime Lck and Fyn for full activation, which is achieved through further phosphorylation. In this manner, CD45 is thought to function by setting an important threshold for T-cell activation.

Laforin

Mutations in the human gene for Laforin, a DS-PTP, have been shown to cause Lafora disease (LD), a progressive form of monoclous epilepsy. The hallmark of LD is the accumulation

of polyglucosan inclusions called Lafora bodies in the cytoplasm of cells of the brain, liver, kidney, skin, skeletal, and cardiac muscle. This human disease phenotype has been replicated in Laforin-deficient mice, through the work of Yamakawa and colleagues. In addition to its DS-PTP domain, Laforin is the only phosphatase in the animal kingdom that possesses a carbohydrate-binding module (CBM), which is required for its association with glycogen particles, and is responsible for targeting the phosphatase to the same subcellular location as

glycogen metabolism. LD was initially proposed to result from abnormal glycogen metabolism, but subsequent studies reported that all enzymes involved in glycogen metabolism from LD patients displayed normal activities. Therefore, Laforin plays a unique and previously unrecognized role in glycogen metabolism that was recently uncovered when Laforin was shown to possess the ability to dephosphorylate phosphoglucans, such as amylopectin and glycogen.

Plants also contain a DS-PTP with a CBM called starch excess 4 (SEX4). Mutations in SEX4 result in an increase in insoluble glucans, a cellular phenotype similar to that seen in LD patients. SEX4 also has the same biochemical properties as Laforin in that it binds glucans and possesses phosphatase activity that releases phosphate from glucans. Although our understanding of the role of glycogen phosphorylation is in its infancy, plant researchers have figured out a mechanistic cause and effect for starch phosphorylation. It appears that phosphorylation of starch solubilizes the outer surface allowing access to the degradation machinery. Then the phosphate is removed by SEX4 so that another round of degradation can occur. Although it follows that mutations in SEX4 result in increased insoluble glucans, it was surprising that this phenotype could be rescued by Laforin expression in plants, making SEX4 and Laforin functionally equivalent. Due to this rare intersection between neuroscience and plant starch metabolism, phosphoglucans can now be added to the physiological substrate list for the DS-PTPs.

PTPs as Drug Targets

Given the potential involvement of PTPs in many aspects of human biology and disease, there is considerable interest in the development of small molecule inhibitors of PTPs for use as therapeutics. In addition to their potential medical value, highly selective and potent PTP inhibitors would be powerful research tools for determining the functions of individual PTPs in mammalian cells. However, the development of specific PTP inhibitors has proved challenging. Like protein kinases, PTPs comprise a large family of enzymes that utilize a common chemical mechanism for catalysis. Accordingly, structure-based drug design will likely be critical to the development of highly specific PTP inhibitors.

Structural studies have suggested a strategy by which inhibitor specificity for individual PTPs might be achieved. Investigations with PTPs have indicated that residues adjacent to the pTyr-binding site play essential roles in achieving substrate specificity and catalytic efficiency. Contemporary work has taken advantage of unique properties of the PTP-1B molecule to develop inhibitors with high selectivity. PTP-1B possesses a second phosphate-binding site on the protein surface, adjacent to its active site. Zhang and colleagues have designed small nonpeptide molecules containing two nonhydrolyzable phosphate moieties. Such molecules inhibit PTP-1B at nanomolar concentrations and are highly selective for this enzyme. High affinity and specificity are achieved by the combined action of the two phosphate moieties, with one binding in the active site and the other at the adjacent site. Such 'bidentate' inhibitor compounds may serve as a model for the development of additional, highly specific

PTP inhibitors, as they target both the active site, which is highly conserved among PTPs, and adjacent portions of the structure, which are less highly conserved.

Proteoglycans

S K Olson and J D Esko, University of California, San Diego, La Jolla, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Chondroitin sulfate A type of glycosaminoglycan defined by the disaccharide unit (GalNAc β 1,4GlcA β 1,3)_n, modified with ester-linked sulfate at certain positions and typically found covalently linked to a proteoglycan core protein.

Dermatan sulfate A modified form of chondroitin sulfate in which a portion of the β -D-glucuronic acid residues are epimerized to α -L-iduronic acid.

Glycan Generic term for a sugar or assembly of sugars, existing either in free form or attached to another molecule.

Glycosaminoglycan Polysaccharide side chains of proteoglycans or free complex polysaccharides composed of linear disaccharide repeating units, each composed of a hexosamine and a hexose or a hexuronic acid.

Glycosyltransferase An enzyme that forms a glycosidic linkage between a sugar and an acceptor.

Heparan sulfate A glycosaminoglycan defined by the disaccharide unit (GlcNAc α 1,4GlcA β 1,4/IdoA α 1,4)_n, containing N- and O-sulfate esters at various positions, and typically found covalently linked to a proteoglycan core protein.

Heparin A type of heparan sulfate made by mast cells that has the highest amount of iduronic acid and of N- and O-sulfate residues.

Hyaluronan A glycosaminoglycan defined by the disaccharide unit (GlcNAc β 1,4GlcA β 1,3)_n that is neither sulfated nor covalently linked to protein, referred to in older literature as hyaluronic acid.

Keratan sulfate A polylactosamine (Gal β 1,4GlcNAc β 1,3)_n with sulfate esters at C-6 of GlcNAc and galactose residues found as a side chain of a keratan sulfate proteoglycan.

Lectin A protein (excluding an antibody) able to bind glycans without causing modification of the glycan structure.

Proteoglycan A protein with one or more covalently attached glycosaminoglycan chains.

Sugar nucleotide Activated forms of monosaccharides, such as UDP-Xyl, UDP-Gal, UDP-GlcA, and UDP-GlcNAc, and UDP-GalNAc, typically used as donor substrates by glycosyltransferases.

Proteoglycan Structure

Glycosaminoglycans

Proteoglycans (PGs) consist of two main structural components – the glycosaminoglycan (GAG) chains and the protein cores.

Three classes of GAG chains are covalently attached to PG core proteins: chondroitin sulfate (CS)/dermatan sulfate (DS), heparan sulfate (HS)/heparin, and keratan sulfate (KS) (Figure 1). Their structure, assembly, and pattern of sulfation distinguish each type of GAG. In addition, vertebrates contain a fourth class of GAGs called hyaluronan (hyaluronic acid, HA), but unlike the other GAGs, HA is not covalently bound to a protein core.

Building blocks

Sugars used in GAG formation include the 5-carbon sugar xylose (Xyl) and the 6-carbon sugars galactose (Gal), glucuronic acid (GlcA), N-acetylglucosamine (GlcNAc), and N-acetylgalactosamine (GalNAc). In order to build the chains, individual sugars are added to a nascent chain in a stepwise manner. The enzymes (glycosyltransferases) that catalyze these reactions use activated nucleotide sugar donors, such as UDP-GlcNAc and UDP-GlcA for HA; UDP-Xyl, UDP-Gal, UDP-GlcA, and UDP-GlcNAc or UDP-GalNAc for HS/heparin and CS/DS; and UDP-Gal and UDP-GlcNAc for the repeating units of KS. PAPS (3'-phosphoadenyl 5'-phosphosulfate) is the universal sulfate donor. With the exception of UDP-Xyl, which is derived from UDP-GlcA in the endoplasmic reticulum (ER), all of the sugar nucleotides and PAPS assemble in the cytoplasm, and transporters shuttle them into the Golgi apparatus or endoplasmic reticulum. Addition of sugar and sulfate residues to the

growing chain releases UDP and 3'-phosphoadenyl 5'-phosphate (PAP), which appear to be converted to uridine monophosphate (UMP) and adenosine monophosphate (AMP) for transport out of the Golgi/ER and subsequent recycling in the cytoplasm.

Hyaluronan

Hyaluronan is structurally the simplest GAG. It consists of repeating disaccharide units of [GlcNAc β 1-4GlcA β 1-3]_n, and does not undergo any further modification. HA is unique among the GAGs in that it does not assemble on a protein core and it is made at the plasma membrane instead of the Golgi apparatus. This orientation facilitates its extrusion from the cell into the surrounding extracellular matrix (ECM). The ECM is the network of PGs, glycoproteins, and fibrous proteins that give strength, support, and structure to the cells embedded within it. HA chains are especially long, typically reaching 10⁴ disaccharides. Due to their length they can intertwine to form a mesh-like material with interesting chemical properties, such as water retention and high viscosity. The turgor properties of the vitreous of the eye, the umbilical cord, and rooster combs reflect the high concentration of HA in these tissues. Several proteins, known as hyalectins, contain a fold (link module) that allow specific interactions with HA. HA helps to organize the extracellular matrix, and can bind to signaling and adhesion receptors on the cell surface, affecting growth and migration.

Chondroitin sulfate/dermatan sulfate

Unlike HA, CS/DS chains (as well as HS/heparin) assemble while attached to a core protein. The chains initiate at serine (Ser) residues of protein cores through the addition of Xyl from UDP-Xyl, followed by addition of two Gal residues, and finally

Figure 1 Classes of glycosaminoglycans. Hyaluronan (HA) is made up of repeating units of GlcNAc and GlcA. Heparan sulfate (HS) and chondroitin sulfate (CS) arise from a common linkage tetrasaccharide precursor linked to a protein core at serine (Ser) residues. HS consists of repeating GlcNAc and GlcA, while CS is composed of GalNAc and GlcA. Keratan sulfate (KS) is composed of GlcNAc and Gal residues attached either to an Asn-linked glycan on a glycoprotein (KSI) or to Ser or threonine (Thr) residues in a mucin-type glycoprotein.

GlcA from their corresponding sugar nucleotides. This linkage tetrasaccharide (GlcA β 1–3Gal β 1–3Gal β 1–4Xyl–) can undergo additional modifications, including sulfation of the Gal residues and phosphorylation of Xyl, which may play a regulatory role in the assembly process. Separate enzymes catalyze each step of the assembly of the linkage tetrasaccharide.

Attachment of GalNAc β 1–4 commits the nascent chain to become chondroitin. The stepwise addition of GalNAc β 1–4 and GlcA β 1–3, catalyzed by the chondroitin synthase enzyme-family, elongates the chain. An average chondroitin chain consists of 40 disaccharides, but the size varies in different tissues. The chondroitin backbone can be modified by sulfation of GalNAc units at C-4 and/or C-6, which tends to occur at most positions along the entire chain. In DS, a subset of D-GlcA units undergoes epimerization to L-IdoA. Epimerization of GlcA to IdoA occurs by stereochemical inversion at C-5 (the proton is axial in D-GlcA but planar in L-IdoA). The extent of epimerization is variable, ranging from 5% to 95% dependent on the tissue origin of the chains. IdoA, and to a lesser extent GlcA, can be sulfated at C-2. In invertebrates, such as *Caenorhabditis elegans* and *Drosophila melanogaster*, most of the disaccharides are nonsulfated.

CS/DS PGs are generally secreted into the extracellular matrix where they perform a variety of structural and developmental roles. The model organism *C. elegans* requires a non-sulfated form of chondroitin for the processes of eggshell assembly and epithelial cell invagination in the vulva. In

vertebrates, CS plays numerous structural roles in cartilage, tendon, and other organized extracellular matrices. In the nervous system, it appears to affect axonal outgrowth and guidance. Very few CS-binding proteins have been described as compared to HS/heparin-binding proteins. Some of the properties of chondroitin are related to its biophysical properties (hydrostatic and electrostatic effects). DS binds with certain growth factors and protease inhibitors involved in hemostasis.

HS/Heparin

HS and heparin synthesis initiates in a manner similar to CS/DS by the assembly of the linkage tetrasaccharide. The nascent chain becomes heparan upon addition of a GlcNAc α 1–4 residue. Polymerization of the chain then ensues by the stepwise addition of GlcA β 1–4 and GlcNAc α 1–4. As the chain elongates, it undergoes a number of modifications. Subsets of GlcNAc residues can be N-deacetylated, N-sulfated, and O-sulfated at the C-3 and C-6 positions. As in the case of CS/DS, epimerization of GlcA to IdoA can occur, but only at residues neighboring GlcNS. Additionally, the uronic acids can be sulfated at C-2. HS chains are generally modified in sections, with highly sulfated blocks interspersed between nonmodified regions. Variable deacetylation, epimerization, and sulfation patterns give rise to specific binding sites for a large number of ligands, including growth factors (fibroblast growth factors (FGFs), Wnts (members of the Wnt family of proteins related to wingless in flies), bone morphogenetic proteins (BMPs)),

anticoagulant proteins (antithrombin III, heparin cofactor II, which also binds DS, and thrombin), and matrix components (e.g., laminin, fibronectin, and some collagens). HS plays a vital role in numerous biological processes involved in cell growth, migration, and differentiation. A human disease called hereditary multiple exostoses (MHE), characterized by bony outgrowths (osteochondromas) on the long bones, is caused by mutation of the enzymes responsible for polymerizing the HS chain (EXT1 and EXT2).

Heparin is a form of HS that has potent anticoagulant activity due to its ability to bind and activate the protease inhibitor, antithrombin, by way of a unique pentasaccharide sequence. In general, heparin is shorter than HS (~14 kDa vs. ~75 kDa) and is much more extensively modified compared to HS, containing as much as 85% GlcNS units and 75% IdoA, whereas HS contains 40–50% GlcNS and 25–40% IdoA. However, like heparin sections of HS chains can be extensively modified by sulfation and epimerization. HS is made by virtually all cells, whereas heparin is made selectively by connective tissue-type mast cells and stored in secretory granules. Therapeutic heparin derives from porcine and equine tissue digests and is fractionated by precipitation methods to yield highly sulfated material with high anticoagulant activity. Therapeutic heparin is one of the largest commercial medicinal natural products in use worldwide. It also has many other useful properties related to blocking inflammation and infection, which are currently in development. Commercial heparin-Sepharose is often used in research laboratories to aid in the purification of proteins.

Keratan Sulfate

KS is classified as a glycoprotein as well as a PG. The chain consists of repeating Gal β 1–4GlcNAc β 1–3 units (*N*-acetylglucosamine), containing sulfate groups in the C-6 positions of Gal and GlcNAc residues. Two forms of KS PGs vary by their linkage to core proteins. In KSI the linkage of the poly-*N*-acetylglucosamine is identical to conventional Asn-linked glycoproteins, whereas in KSII the linkage is identical to that found in mucins (Figure 1). Like HS, the disaccharide units of KS can be unsulfated, monosulfated, or disulfated. KS is expressed in cartilage and a number of epithelial and neural tissues, playing a role in events as diverse as collagen fiber assembly, wound healing, and embryogenesis. They are also present in neurosecretory vesicles, suggesting unique roles in vesicle formation and neuronal activity.

Protein Cores

With the exception of HA, all GAGs are synthesized while attached to a protein core. Some PG cores serve functional roles independent of the associated GAG chains by binding to ECM molecules and the cytoskeleton. The number of GAG chains carried by individual PGs depends on the number of attachment sites, ranging from a single chain (decorin) up to 100 chains (aggrecan) (Table 1). Most PGs contain multiple glycosylation sites, any or all of which may be used. A loose consensus sequence has been identified for HS and CS glycosylation sites on the protein core. Xyl is added to Ser residues

that are followed by glycine (Gly), typically flanked by two or more acidic amino acids (Asp or Glu). The factors that regulate the efficiency of initiation are unknown. Evidence also exists that the presence of hydrophobic residues near the attachment sites, the density of attachment sites, as well as inhibitory sequences in the protein cores determine the selection of sites for the assembly of HS/heparin or CS/DS.

PG Families

More than 25 PGs have thus far been identified in mammalian systems (Table 1), and many fall into gene families based on sequence homologies. Some PGs carry a single type of GAG, whereas others can be hybrid molecules carrying HS and CS, or CS and KS. Many PGs also carry other types of O-linked and N-linked glycans. Some PGs are large multidomain molecules reaching masses of 400 kDa, with subdomains of varying functions (e.g., cell attachment, association with other ECM proteins, binding of growth factors, and intrinsic growth modulatory activities), while others have small masses around 10 kDa. While structurally and functionally diverse, they can be classified into the following families based on localization and homology. Note that invertebrates also express numerous PGs, including heparan sulfate proteoglycans (HSPGs) related to those found in vertebrates and chondroitin PGs that are unique.

Secreted and Matrix PGs

The majority of PGs secreted into the ECM carry CS or DS chains. This group includes the small interstitial PGs, the aggrecan family, and secretory granule PGs, such as serglycin. Perlecan, agrin, and collagen XVIII are the only known HSPGs specifically secreted into the ECM. However, some membrane HSPGs (e.g., syndecans and glypicans) can be shed from the cell surface and the ectodomains can become part of the ECM or accumulate in extracellular fluids.

Small Interstitial PGs

This class of PGs includes proteins with leucine-rich repeats flanked by cysteines in their central domain, the so-called small leucine-rich proteoglycans (SLRPs). The family has at least nine members, and all carry either CS/DS or KS GAG chains. Members include decorin and biglycan, which interact with collagen in the matrix. Much work to date has concentrated on understanding the role of these PGs in stabilizing and organizing collagen fibers. In decorin, this activity appears to be dictated by the PG core because removal of the GAG chains fails to affect fibrillogenesis. Mice lacking the decorin PG live to adulthood but show a fragile skin defect, and exhibit great variation in collagen fibril diameter and spacing. Human patients with a mutation in the decorin gene develop congenital stromal corneal dystrophy, characterized by opacity of the cornea due to irregular spacing of collagen fibrils. KSPGs also maintain the register of collagen fibers in the cornea, which is required for transparency and curvature. Humans with a mutation in the keratocan gene develop Cornea plana 2, a recessive disease in which patients exhibit severe far-sightedness due to defects in corneal curvature. Decorin is also able to bind

Table 1 Proteoglycan families

<i>Class</i>	<i>Family</i>	<i>Proteoglycan</i>	<i>Core mass (kDa)</i>	<i>Chain #</i>	<i>Chain type</i>	<i>Tissue</i>	<i>Human disease</i>
Matrix/secreted	Small interstitial	Decorin	36	1	CS	Connective tissue cells	Congenital stromal corneal dystrophy

		CD47	35		HS/CS	T-cells	

transforming growth factor beta (TGF- β), serving as a sink to keep the growth factor sequestered.

Aggrecan family

The Aggrecan family of PGs includes aggrecan, versican, brevican, and neurocan. All four members share these common features: the N-terminal domain is able to bind HA, the central region contains GAG attachment sites, and the C-terminal domain contains a C-type lectin domain (lectins are nonimmunoglobulin, nonenzymatic proteins that bind sugar chains). Aggrecan is the most well-known member of this family, since it is the major PG present in cartilage. It contains by far the largest number of GAG chains, as many as 100 CS and KS chains per protein. It complexes with HA in the ECM and draws water into cartilage, thereby providing the ability to resist compressive forces. Mutations in the human aggrecan gene have been linked to two different forms of spondyloepimetaphyseal dysplasia, a skeletal dysplasia characterized by short stature (dwarfism) and other problems associated with the importance of cartilage in bone development. Versican is the next largest member of the aggrecan family with a mass of 265 kDa, and it also undergoes alternative splicing events that generate smaller proteins. Roles in neural crest cell and axonal migration have been suggested. Human patients with mutations in the versican gene exhibit Wagner syndrome, a should be vitreoretinopathy that causes lesions of the vitreous of the eye, and occasionally retinal detachment and cataracts. Neurocan and brevican are both localized to the brain. Neurocan is expressed in the late embryonic central nervous system (CNS) and acts to inhibit neurite outgrowth. Brevican is expressed in the terminally differentiated CNS, particularly in perineuronal nets.

Basement membrane PGs

The basement membrane is an organized layer of ECM that separates epithelial and endothelial cells from the fibrous matrices of connective tissues. It consists of laminin, collagen, nidogen, and usually HSPGs. Basement membranes contain three types of large PGs – perlecan, agrin, and collagen XVIII – each containing one to three HS chains (though perlecan has been shown to carry CS on occasion, e.g., in rib cartilage). Perlecan is the largest known HSPG with a mass of 400 kDa and is a modular protein with multiple domains that serve numerous functions. It is present in the pre-implantation blastocyst and endothelial cells, and appears to play a role in embryogenesis and tissue morphogenesis. In humans, mutations in the perlecan gene cause Schwartz–Jampel syndrome (SJS) and Silverman–Handmaker dyssegmental dysplasia (DDSH), which are skeletal dysplasias of varying severity and can cause either short stature (SJS) or neonatal lethal short-limbed dwarfism (DDSH). These disorders highlight the importance of perlecan in cartilage and bone development. Agrin is a well-characterized PG that acts in the nervous system by aggregating acetylcholine receptors at the neuromuscular junction, and is additionally expressed in the renal tubules where it plays an important role in determining the filtration properties of the kidney. Mutations in the human agrin gene cause congenital myasthenic syndrome, which is characterized by muscle weakness due to defects at the neuromuscular junction. Collagen XVIII is prevalent in the liver in the space of Disse that separates the endothelial cells of the sinusoids from

the hepatocytes, and throughout the vasculature. In human patients, mutations in the collagen XVIII gene have been associated with the vitreoretinal degeneration, retinal detachment, and near-sightedness associated with type I Knobloch syndrome. Homologs of the basement membrane PGs exist in flies and worms.

Secretory granule PGs

Serglycin is the main PG localized to intracellular cytoplasmic secretory granules. It is synthesized by endothelial, endocrine, and hematopoietic cells, and it can carry CS or heparin chains. Serglycin is stored in secretory granules until the host cell becomes activated, resulting in secretion of granular contents into the surrounding environment. Serglycin may play a role in packaging granular contents, maintaining granule proteases in an inactive state, and regulating activities after secretion, such as coagulation, host defense, and wound repair. Heparin, the highly sulfated form of HS, is thought to be made exclusively on serglycin present in mucosal mast cells, but macrophages also produce a highly sulfated form of HS.

Membrane-Bound PGs

Many PGs reside in cell membranes as type I transmembrane proteins (e.g., syndecan family) or glycosylphosphatidylinositol (GPI)-linked proteins (e.g., glypican family).

Syndecans

In syndecans, a short hydrophobic domain spans the membrane, linking the larger extracellular domain containing the GAG attachment sites to a smaller intracellular cytoplasmic domain. There are four members in mammalian systems, whereas lower organisms such as flies and worms contain only one homolog. They can carry HS and/or CS chains, which bind a wide range of extracellular ligands such as growth factors and matrix molecules. These interactions likely account for the requirement of syndecans at numerous stages of embryonic development and in the adult animal. Syndecans can additionally coordinate signals from the extracellular environment to the intracellular cytoskeleton via their cytoplasmic tails. For example, binding of a ligand to a GAG chain can induce oligomerization of syndecans at the cell surface. This leads to recruitment of factors at the cytoplasmic tail of syndecan, such as kinases (e.g., c-Src), PDZ-domain proteins, or cytoskeletal proteins. The recruitment of cytosolic proteins in turn triggers a signal that leads to actin filament assembly. Proteolytic cleavage of the syndecans occurs, resulting in release of the ectodomains bearing the GAG chains. These ectodomains can have potent biological activity. Human genetic studies have identified single nucleotide polymorphisms (SNPs) in the syndecan-3 (SDC3) gene. In one study, a particular SNP was closely correlated with obesity in Korean subjects, suggesting that the role of SDC3 polymorphisms in progression to obesity may have ethnic differences. In mice, alterations of syndecan-1 in hepatocytes result in hypertriglyceridemia.

Glypicans

The glypican family of cell-surface PGs is involved in numerous aspects of animal development. The C-terminus is embedded

in the membrane by a hydrophobic GPI-linked anchor, and thus the glypicans do not have a cytoplasmic tail like the syndecans. The N-terminal portion of the protein is globular and has been shown to carry only HS chains *in vivo*. The glypicans bind a wide array of factors that are essential for the development and morphogenesis. Their roles in growth factor signaling potentially include both positive and negative regulation. HS chains are able to positively promote signaling by bringing a ligand and its receptor into close proximity. On the other hand, HS chains could negatively regulate signaling by binding a particular ligand and preventing its diffusion or interaction with a receptor.

Six glypican family members exist in mammals, two in flies, and one in worms. Glypican-3 (GPC3) is the best-studied member of the family. Human patients lacking functional GPC3 exhibit Simpson–Golabi–Behmel syndrome, which is characterized as an overgrowth disorder. The overgrowth phenotype suggests that GPC3 normally functions to inhibit cell proliferation, likely mediated at the level of growth factor signaling at the cell surface. Mutation of GPC6 causes omodysplasia, a condition where the arms and/or legs are stunted in growth and appear club-like. This condition is thought to be caused by misregulated growth factor signaling at the bone growth plate, preventing proper chondrocyte differentiation. Mutation of GPC1 decreases the size of the brain through regulation of fibroblast growth factor signaling in early neurogenesis.

Miscellaneous membrane PGs

A number of membrane PGs do not show homology to syndecans or glypicans, but are expressed on the surface of many different cell types. The CSPG NG2 is a surface marker expressed on stem cell populations that are able to divide throughout an organism's life, including cartilage chondroblasts, myoblasts, endothelial cells of the brain, and glial progenitors. It has been shown to play a role in angiogenesis and inhibits neurite outgrowth. CD44 is a transmembrane cell-surface receptor that plays a role in processes as diverse as immune function, axon guidance, and organ development. CD44 is considered a PG since it can carry GAG chains in certain cell types, such as lymphocytes. It is also an HA-binding protein. The GAG chains allow CD44 to interact with ECM proteins and growth factors. Neuropilin-1 is a subunit of receptor complexes that bind to semaphorins and vascular endothelial growth factors (VEGFs).

Processing

PGs are born in the ER, undergo glycosylation and sulfation in the Golgi, and appear at the cell surface or in the extracellular matrix. However, important steps of the PG life cycle also occur at the cell surface and other intracellular compartments.

Cell-Surface Desulfation

Although all of the sulfation reactions occur in the Golgi apparatus as the chains assemble prior to secretion, a family of cell-surface endosulfatases (Sulfs 1 and 2) has been identified that removes sulfate groups from the C-6 position of glucosamine residues in HS. Sulfs can promote Wnt growth

factor signaling through HS in a finely tuned manner by desulfating HS at the appropriate time and place. Sulfs also can decrease other growth factor signaling events.

Shedding and Heparanase Cleavage

PGs are turned over on a continual basis (Figure 2). Both the syndecans and glypicans undergo proteolytic cleavage and shedding at the cell surface, mediated by one or more of the matrix metalloproteases. This process appears to be regulated and can be induced by foreign organisms that exploit the ectodomains for colonization. Secreted enzymes called heparanases can cleave HS chains into fragments at defined sites, liberating small HS fragments. Cells might use heparanase during tissue remodeling and migration, for example, during metastasis.

Endocytosis

Cells internalize HA, CS/DS, and KS PGs by endocytosis, most likely by macropinocytosis. Incoming vesicles containing the PGs fuse with the lysosomes where sulfatases and exoglycosidases degrade the chains completely, while proteases degrade the core proteins. The liberated sugars (GlcNAc, GalNAc, Gal, and Man) and amino acids can then be recycled for the formation of new GAG chains and PGs, whereas the uronic acids and Xyl are thought to undergo oxidative catabolism since no

Figure 2 Life cycle of a proteoglycan. Proteoglycans are predominantly synthesized in the Golgi apparatus (G). A mature proteoglycan can be embedded in the plasma membrane, stored in secretory granules (SG), or secreted into the extracellular matrix (ECM) or basement membrane (BM). Degradation of proteoglycans begins with endocytic internalization, followed by cleavage of the GAG chains and protein core by glycosidases and proteases, respectively, in endosomes (E) and lysosomes (L). Nucleus is denoted as N.

salvage pathways for these sugars have been identified. Lysosomes also contain enzymes for degrading HA and CS/DS. Many ligands that bind to cell-surface PGs can enter the cells during the internalization process. In fact, this mechanism is a major route for clearance of triglyceride-rich lipoproteins in the circulation (remnant lipoprotein receptors). Endocytosis of ligands bound to PG receptors may be a general function of continuous turnover of the PGs. Disruption of this pathway leads to lysosomal-storage disorders known as the mucopolysaccharidoses (MPS), which have devastating health consequences for afflicted individuals.

Glossary

Antiporter A membrane-bound proteinaceous entity that catalyzes transmembrane transport of a molecule (or ion) in one direction with obligatory linkage to transport of another molecule (ion) in the opposite direction. Examples are the adenine nucleotide ($\text{ADP}^{3-}/\text{ATP}^{4-}$) and inorganic phosphate ($\text{H}_2\text{PO}_4^-/\text{OH}^-$) carriers of mitochondria and Na^+/H^+ exchangers of bacteria. Note that the former is electrogenic, whereas the two latter are electroneutral.

Electron carrier A protein, a prosthetic group in a protein, or a cofactor, that may exist in an oxidized and a reduced form, which differ by the absence or presence of an electron.

F_1F_0 ATP synthase The membrane-bound enzyme complex that catalyzes ATP synthesis driven by protonmotive force in mitochondrial and bacterial oxidative phosphorylation, and in photosynthesis.

Hydrogen carrier A protein, a prosthetic group in a protein or a cofactor, that may exist in an oxidized and a reduced form, which differ by the absence or presence of hydrogen (usually two hydrogen atoms, such as ubiquinone/ubiquinol).

Mitochondrial membrane Usually refers to the highly invaginated inner (cristae) membrane of mitochondria that harbors the protein complexes of oxidative phosphorylation, and which is relatively impermeable to ions.

Proton pump A membrane-bound enzyme complex that catalyzes translocation of protons across a membrane against a proton electrochemical gradient, driven by an exergonic reaction.

Protonmotive force Equals the electrochemical proton gradient across a membrane, being the sum of a concentration term (the pH-gradient) and an electric term (the membrane potential).

Q-cycle The ubiquinone cycle is the name of the mechanism by which the cytochrome bc_1 complex and the related photosynthetic cytochrome b_6f complex catalyze redox-linked generation of protonmotive force.

Redox couple The collective term for the oxidized and reduced forms of an electron or hydrogen carrier.

Redox loop A mechanistic principle proposed by Peter Mitchell, according to which redox reactions in respiration and photosynthesis are orientated in membranes in such a way as to transfer neutral hydrogen in one direction and negatively charged electrons in the opposite direction, leading overall to net translocation of protons.

Redox potential E_h (in volts, usually relative to NHE, the normal hydrogen electrode) reports the tendency of a redox couple to accept an electron. At thermodynamic equilibrium, all redox couples experience the same redox potential.

Aerobic organisms depend on the availability of molecular oxygen (O_2), which serves as a sink for electrons released upon oxidation of hydrocarbon foodstuffs in catabolism, a series of events referred to as cellular respiration. Transfer of these electrons to O_2 , reducing it to water in the final stage, is an exergonic process (i.e., it proceeds with decrease of free energy) that is catalyzed in the inner mitochondrial membrane, or in the cell membrane of aerobic prokaryotes, by transmembrane protein complexes that are collectively called the respiratory chain. The three enzymes forming the respiratory chain are able to convert energy freed from the electron-transfer reactions, including the chemistry of O_2 reduction to water, into an electrochemical proton gradient across the membrane, which drives the synthesis of adenosine triphosphate (ATP) (called oxidative phosphorylation) and membrane transport reactions. Here we briefly define the basic mechanistic principles by which the respiratory chain creates a proton gradient, which is the basis of primary energy conservation in aerobic organisms.

The Proton-Translocating Respiratory Chain, an Overall Perspective

The respiratory chain is a functional concept (Figure 1). Reducing equivalents are fed into the chain in the form of a reduced water-soluble cofactor, nicotinamide adenine dinucleotide

(NADH). NADH is produced from its oxidized counterpart, NAD^+ , especially in Krebs' cycle (also known as the citric acid or the tricarboxylic acid cycle) and during fatty acid oxidation. Dehydrogenases catalyze a reaction

where AH_2 is the hydrogenated metabolite substrate and A its oxidized form. Of the two hydrogen atoms removed from the substrate, a hydride ion is utilized for reduction of NAD^+ , while a proton is liberated into the medium due to the acid-base properties of NADH. At neutral pH, the midpoint oxidoreduction or redox potential of the NAD^+/NADH couple is -320 mV (this is the $E_{m,7}$ value), relative to the normal hydrogen electrode (NHE). NADH transfers its reducing equivalents to the first component of the respiratory chain, for example, complex I, which functions as an NADH-ubiquinone oxidoreductase. Ubiquinone, the acceptor of the reducing equivalents, is a highly apolar hydrogen carrier diffusing within membranes. The redox reaction of the ubiquinone/ubiquinol couple

has an $E_{m,7}$ of $c. 60$ mV. Ubiquinone is present in the inner mitochondrial membrane at a concentration far higher than the respiratory chain complexes. Under standard conditions ($\text{pH}=7$ and equal concentrations of oxidized and reduced

Figure 1 A schematic representation of the three proton-translocating enzyme complexes forming the respiratory chain. The flow of electrons through the complexes as well as the translocation of protons across the membrane is represented by black arrows. The structures used are as follows: complex I from *Thermus thermophilus* (PDB ID 3M9S); complex III (dimeric) from bovine heart (PDB ID 1BGY); cytochrome *c* from equine heart (PDB ID 1HRC); and complex IV from bovine heart (PDB ID 1OCC). AH_2 and *A* represent the reduced and oxidized forms of an NAD^+ -linked metabolic substrate (malate and oxaloacetate, for example).

forms), there is hence a redox potential difference ($\Delta E_{m,7}$) of ~ 380 mV between the donor and acceptor ends of complex I. Or put differently, there is a driving force of this magnitude for the electrons to be transported from NADH to ubiquinone, the conversion to a standard Gibbs free energy change ($\Delta G'_0$) being of the form

$$\Delta G'_0 = -nF\Delta E_{m,7} \quad [3]$$

where n is the number of electrons to be transferred and F the Faraday constant, the approximate value of which is $23 \text{ kcal mol}^{-1} \text{ V}^{-1}$.

Ubiquinone may also be reduced by other routes than via complex I, for example, by succinate via the succinate dehydrogenase complex, also called complex II. However, complex II is not a part of the respiratory chain because the reaction catalyzed does not conserve redox energy as proton-motive force. Succinate dehydrogenase is the only enzyme of the Krebs' cycle that is bound to the inner mitochondrial membrane, the reason for which is the location of the hydrogen acceptor, ubiquinone.

Ubiquinone is a point in the respiratory chain into which hydrogen is transferred from different branches of catabolism, as is the case for NAD^+/NADH . In animal mitochondria reduced ubiquinone is oxidized further by a single pathway, via the respiratory chain complexes III and IV (see below), whereas alternative routes of ubiquinol oxidation are found in plant mitochondria and in many aerobic bacteria. Complex III is a ubiquinol-ferricytochrome *c* oxidoreductase, also known as the cytochrome bc_1 complex. Here, the water-soluble hemoprotein ferricytochrome *c* is the acceptor, this time a pure electron acceptor

so that oxidation of the hydrogen in ubiquinol must result in net release of protons. The $E_{m,7}$ of cytochrome *c* is $c. 220$ mV when associated with the mitochondrial membrane. The last enzyme

in the respiratory chain, complex IV or cytochrome *c* oxidase, catalyzes oxidation of cytochrome *c* by molecular oxygen. The $E_{m,7}$ of the $\text{O}_2/\text{H}_2\text{O}$ redox couple is 810 mV under standard conditions (1 atm-O_2 , or $\sim 1.2 \text{ mmol l}^{-1}$ in pure water at 25°C).

The chemical reaction catalyzed by the mitochondrial respiratory chain

thus covers a standard redox potential span of $c. 1.15$ V from NADH to O_2 . The actual redox potential span (ΔE_h) is offset from $\Delta E_{m,7}$ by the concentration terms of the oxidized and reduced forms of reductant and oxidant and constitutes the driving force for proton translocation across the membrane, and thereby generation of an electrochemical proton gradient (i.e., protonmotive force). The stoichiometry of proton translocation in the respiratory chain is 10 H^+ per two redox equivalents, that is,

where AH_2 and *A* are again the reduced and oxidized forms of an NAD^+ -linked substrate, respectively. The maximum protonmotive force created by the mitochondrial respiratory chain is $c. 230$ mV, under which conditions the rate of respiration comes to a minimum and ATP synthesis stops. With a stoichiometric proton pumping efficiency of $5\text{H}^+/\text{e}^-$ and $5 \times 230 \text{ mV} = 1.15$ V, it follows that this is a state close to thermodynamic equilibrium between the driving and the driven reactions.

Redox Loop versus Proton Pump

In the respiratory chain, electrons, ultimately used to reduce molecular oxygen, travel through a series of redox centers with increasing electron affinities, while energy liberated during the

Figure 2 Schematic representation of the redox-loop mechanism. Sequential movement of neutral hydrogen atoms and charged electrons in opposite directions across the membrane results, in effect, in translocation of protons.

process is utilized for translocation of protons across the membrane from the mitochondrial matrix (negatively charged N-side) to the intermembrane space (positively charged P-side) (Figure 1). Peter Mitchell's chemiosmotic theory was based on the postulate of orientated redox chemistry in the respiratory chain in such a way that the neutral element of hydrogen is translocated from the N- to the P-side of the membrane, whereas the negatively charged electrons are translocated in the opposite direction, from P to N (Figure 2). In such a system, there is an alternate involvement of hydrogen and electron carriers as redox-active elements, of which ubiquinone and cytochrome *c* are examples, respectively. It is important to note here that in such a redox-loop arrangement of the respiratory chain, there is actually no proton translocation in the microscopic/mechanistic sense, even though the overall effect will be a transfer of hydrogen ions across the membrane. Instead, the body of the proton is transferred toward the P-side as the electrically neutral hydrogen atom (i.e., in conjunction with an electron), and the translocation of electrical charge is due to transfer of the electron in the opposite direction.

By contrast, in a redox-driven proton pump the chemical reaction is coupled to and drives true proton translocation across the membrane. Hence, the principle and the mechanistic requirements are very different from those of a redox loop. As it has turned out, only the protonmotive principle of the cytochrome *bc₁* complex is of the redox-loop type, employing a fairly complicated cyclic mechanism (see below). On the other hand, both complexes I and IV are true redox-linked proton pumps even though some redox-loop features are nevertheless present in the latter case.

Complex I or NADH: Ubiquinone Oxidoreductase

It has been established that two protons are translocated across the membrane per electron transferred from NADH to ubiquinone, when catalyzed by complex I:

We specify that reduction of NAD^+ by hydrogenated substrates in the mitochondrial matrix is followed by reduction of complex I by NADH, where subsequent to reduction of flavin

mononucleotide (FMN; the first acceptor of reducing equivalents in complex I; purple structure in Figure 1), the reducing equivalents are accepted by iron-sulfur (Fe/S) centers (green structures; Figure 1). The Fe/S centers act as pure electron carriers, so that ultimately the two protons released on the N-side of the membrane during oxidation of AH_2 via NAD^+ are consumed when ubiquinone is reduced (Figure 1).

These protonations and deprotonations should not be confused with the translocation of two protons per electron across the membrane (or 4H^+ translocated/NADH oxidized), which is the proton-pumping activity of complex I and its contribution to generation of protonmotive force (Figure 1).

As has been revealed by electron microscopy and recent X-ray structures, complex I is L-shaped consisting of a membrane-intrinsic arm and an extrinsic domain attached to it on the N-side of the membrane (Figure 1). Moreover, it has been established that all known redox centers are located in the extrinsic domain, for example, the FMN cofactor and an array of 8 (in some species 9) Fe/S clusters. A binding site for ubiquinone has been located near the interface between the extrinsic and intrinsic domains.

The membrane domain consists of a number of conserved subunits, three of which are homologous to Na^+/H^+ antiporters and hence likely to be involved in the proton-pumping mechanism. Very recent X-ray structures of the membrane domain show a remarkably long α -helix positioned parallel to the membrane, which has been proposed to act as a piston-like element in the redox-linked proton pump mechanism. Such a mechanic element is of interest also, because it is reminiscent of the mechanical coupling between proton translocation and ATP synthesis in the F_1F_0 ATP synthase, the enzyme responsible for phosphorylation of adenosine diphosphate (ADP) to form ATP. However, to date there is no direct evidence for such a function in complex I, and the mechanism of generation of protonmotive force is, in this case, far less elucidated than the corresponding mechanisms for complexes III and IV.

Complex III or Ubiquinol:Ferricytochrome *c* Oxidoreductase

Complex III is unique in the respiratory chain in that it switches from a hydrogen carrier as the donor (ubiquinol) to an electron carrier as the acceptor (ferricytochrome *c*), which means that the overall process must be associated with net release of $2\text{H}^+/2\text{e}^-$:

However, the actual reaction catalyzed is far more complicated than implied by eqn [8], which applies only in solution. Especially, it should be noted that the substrate protons of eqn [8] have no protonmotive function, because they are released from mitochondria into the strongly buffered intermembrane space (from bacteria into the outside world), and do not significantly contribute to either the ΔpH or membrane potential terms of the protonmotive force. The true reaction of complex III in the membrane can be described as

where two of the four protons released on the P-side are the substrate protons of eqn [8]. The question then arises as to how two protons are translocated across the membrane linked to the two-electron oxidation of ubiquinol by ferricytochrome *c* (eqn [9]). The solution to this problem is basically understood today and is a key part of the history of the field of molecular bioenergetics.

Complex III is characterized by having two ubiquinone binding sites, Q_o near the P-side of the membrane and Q_i near the N-side (Figure 3). Two *b*-type heme groups, b_L and b_H (for low and high redox potential, respectively), connect the sites from an electron-transfer point of view. A high-potential iron-sulfur center, the Rieske Fe/S site, has alternate positions, either near site Q_o or close to the acceptor cytochrome c_1 .

The two-electron donor ubiquinol (QH_2) is oxidized at the Q_o site by a unique mechanism in which the path of the two electrons is bifurcated; one electron is donated to the Fe/S center and the other to heme b_L in the vicinity. Simultaneously, the two protons of QH_2 are released to the P-side of the membrane. The low-potential heme b_L donates the electron to the high-potential heme b_H on the N-side and equilibrates with bound ubiquinone in the Q_i site next to it. The full catalytic cycle requires oxidation of a second molecule of QH_2 in the same manner as the first, whereby arrival of the second electron to the Q_i site leads to uptake of two protons from the N-side yielding QH_2 as the product. This so-called Q-cycle mechanism, which is summarized by eqn [9] (see Figure 3), has been well established for quite some time, and is fully consistent with the X-ray diffraction structures of complex III that were solved much later.

It is important to note that complex III is not a proton pump in the mechanistic sense, but a Mitchellian redox loop (see Figure 2), where QH_2 carries hydrogen from the N- to the P-side of the membrane, electrons are carried in the opposite direction via the *b*-type hemes, protons are released on the P-side when QH_2 is oxidized by pure electron acceptors, and taken up on the N-side when Q is reduced by the electron-donating heme b_H . From a bioenergetic viewpoint, it is also important that the effective stoichiometry of proton translocation is $1H^+/e^-$ (as it must be in a redox loop), even though $2H^+/e^-$ are released on the P-side of the membrane (see above).

Complex IV or Cytochrome *c* Oxidase

Contrary to complex III, the reaction catalyzed by complex IV uses an electron carrier as a donor of reducing equivalents (cytochrome *c*), but a hydrogen-accepting entity (O_2) as the acceptor. This means that the overall chemical reaction will consume $2H^+/2e^-$. In addition, the energy released in this reaction is used to translocate one proton across the membrane for every electron (the proton-pumping function):

The active site of complex IV consists of a binuclear heme-copper center (heme a_3/Cu_B) which binds O_2 in its ferrous/cuprous state in much the same general fashion as dioxygen is bound to heme iron in oxyhemoglobin and oxymyoglobin. Electrons are donated to this center, one at a time, from

Figure 3 The Q-cycle mechanism. The structure of complex III is depicted in gray while the soluble cytochrome *c* is shown in green. Prosthetic groups of complex III are labeled and marked with black arrows. The binding sites for the quinone molecules are marked by yellow boxes; the Q_o -site resides close to the P-side of the membrane (above) while the Q_i -site is located near the N-side (below). The dashed arrows represent the movements of the quinone molecules. The flow of electrons is shown by red arrows, and the protons involved in the mechanism are represented by blue arrows. (a) A quinol molecule enters the Q_o -site while a quinone molecule occupies the Q_i -site. Oxidation of the quinol in the Q_o -site results in the release of two electrons, one of which is used to reduce quinone in the Q_i -site to semiquinone while the other travels via the Rieske Fe-S center and heme c_1 to the soluble cytochrome *c*. The two protons liberated in the process are released on the P-side of the membrane. (b) In the next step, the entrance of the second quinol molecule to the Q_o -site leads to the same reaction sequence which results in reduction of the semiquinone to quinol in the Q_i -site with uptake of two protons from the N-side of the membrane.

another heme (heme *a*) that lies in the vicinity, and which receives electrons from a bimetallic copper center, Cu_A , that lies at the P-side interface. Cu_A in turn, receives electrons from the donor, soluble cytochrome *c* (Figure 1).

It may be noted as a curiosity that complexes III and IV function together as one complete Mitchellian redox loop: oxidation of ubiquinol by ferricytochrome *c* catalyzed by complex III releases $1\text{H}^+/\text{e}^-$ on the P-side of the membrane (see above). The resulting electron is then transferred across part of the membrane to the heme a_3/Cu_B site of complex IV, where it reduces $1/4 \text{O}_2$ to $1/2 \text{H}_2\text{O}$ with the aid of one proton taken from the N-side. However, the Q-cycle mechanism in complex III ensures protonmotive activity of this complex by itself (see above), and complex IV adds a proton pumping activity that doubles its protonmotive efficiency so that it is $2\text{H}^+/\text{e}^-$, that is, twice that of complex III. Note that $2\text{H}^+/\text{e}^-$ is the effective protonmotive efficiency of complex IV even though only $1\text{H}^+/\text{e}^-$ is released on the P-side.

The mechanism by which protons are pumped by complex IV is electrostatic in nature. An electron in the heme *a* domain increases the proton affinity (pK_a) of a proton loading site (or pump site), which has not been definitely identified but has been suggested to be the A-ring propionate of heme a_3 . The increased pK_a leads to uptake of a proton from the N-side into that site, uptake from the P-side being too slow to compete. Loading the pump site with a proton increases the electron affinity ($E_{m,7}$) of the metals in the binuclear site, which results in transfer of the electron to that site, which further increases the pK_a of the pump site. However, electron transfer to the binuclear site causes an even larger increase of the pK_a of the binuclear center, which leads to uptake of a second proton to that site from the N-side of the membrane. The charge of the electron at the binuclear site is thus neutralized by the second proton, which is one of the four reaction steps in which O_2 is

reduced to two molecules of water at this location. Electrical neutralization of the binuclear site results in lowering of the initial proton affinity of the pump site, with the consequence that the proton in the latter is released by electrostatic repulsion to the P-side of the membrane. If it were released to the N-side, the pump mechanism would be compromised, and this is prevented by a gating function in which the position of the electron (at heme *a* or at the binuclear site) controls the kinetic barrier of proton transfer between the N-side of the membrane and the pump site.

Glossary

Aromatic amino acid Aromatic compounds are cyclic compounds containing double bonds so that their three-dimensional structure is planar. Amino acids are small molecules, which consist of a central carbon atom, tetrahedrally bonded to a carboxylic acid group, an amino group, a hydrogen, and a fourth group, often called an R group; in the aromatic amino acids, it is this R group which is aromatic.

Heme A large planar heterocyclic compound consisting of four bridged pyrrole rings which binds

Fe in biological systems for the transport or reactivity of oxygen.

Heterocycle A ring-shaped compound made up of more than one kind of atom.

Pyrimidine and pyrazine Organic heterocyclic compounds consisting of a six-membered ring with two nitrogen atoms separated by one carbon in pyrimidine and two carbons in pyrazine.

Radical An atom or group of atoms possessing an odd (unpaired) electron.

The pteridines are a group of heterocyclic compounds containing a wide variety of substitutions on the basic compound pterin. Pterin itself is composed of a pyrazine ring and a pyrimidine ring; the pyrimidine ring has a carbonyl oxygen and an amino group. The biosynthesis of pterins begins with the molecule guanosine triphosphate (GTP); the enzyme which controls the conversion of GTP to pterin, GTP cyclohydrolase, is found in both prokaryotes and eukaryotes. Pterins were first discovered in the pigments of butterfly wings and they perform many roles in coloration in the biological world. Pterins also function as cofactors in enzymatic catalysis. Folates, 'conjugated' pterins which contain *p*-amino benzoic acid and glutamates in addition to the pterin ring system, are critical compounds in methyl transfer biochemistry. Tetrahydrobiopterin, the major unconjugated pterin in vertebrates, is involved in the hydroxylation of aromatic compounds and synthesis of nitric oxide. Molybdopterin – which contains pterin, a third heterocyclic ring containing an ether oxygen and two thiol substitutes, and molybdenum – is involved in biological hydroxylations, reduction of nitrate, and respiratory oxidation.

The name pteridine refers to the heterocyclic aromatic compound shown in [Figure 1](#), composed of a pyrimidine ring fused to a pyrazine ring. However, the word pteridines has come to stand for an entire group of naturally occurring compounds. Their structures are based upon pteridine, but they have substituents on the pyrimidine ring: an amino group or a carbonyl at position 2 and a carbonyl group at position 4 (position numbers as shown in [Figure 1](#)). Pterin contains the amino substituent at position 2; all pterins are derivatives of this molecule. Most of the naturally occurring pteridines are pterins. The first pterins to be studied, leucopterin and xanthopterin, were pigments isolated from butterfly wings, by Sir Frederick Gowland Hopkins at Cambridge University in the late nineteenth century. Their names are derived from the Greek words for wing, *pteron*, white, *leukos*, and yellow, *xanthos*.

Pterins are referred to as being conjugated or unconjugated. The conjugated pterins are folates, derivatives of folic acid. They contain a *p*-aminobenzoate substituent at the 6-position and one or more glutamate residues. The folates are discussed

elsewhere in this encyclopedia. As a general but not fast rule, folates are involved in one-carbon transfers in metabolism and pterins are involved in oxygenation reactions or in pigmentation.

Distribution of Pterins in Nature

Pterins are found in all living organisms, from bacteria, blue-green algae, and trypanosomes, to mammals; they have also been detected in the chloroplasts of spinach leaves and the cotyledons of pea sprouts. A wide variety of pterins exist in bacteria, such as the various pterins with three-carbon side chains of *Escherichia coli*, the glucuronidated pterins of *Bacillus subtilis*, the three ribityl pteridines of the marine bioluminescent bacterium *Photobacterium phosphoreum*, the molybdopterins of photosynthetic bacteria, and the tetrahydrodromethanopterins of methanogenic bacteria.

As pigments, pterins are not only found in butterfly wings, but also in moth heads, silkworm skin, grasshopper bodies, and honeybee larvae. A list of examples demonstrates the very wide use nature has made of pterins in coloration; diversity is found in species distribution, chemical structures, and hue. Unusual dimeric pterins are found in the eyes of the fruit fly, *Drosophila*. A blue pigment in the roundworm *Ascaris lumbricoides* contains biopterin. Pterins are common in the skins of amphibians and fish, and photolabile pterins are found in some amphibians' eyes. The red color of some salmon, the Siamese fighting fish, and the red lizard *Anolis*, is due to pterins, as is the green color of some snakes.

Clearly, pterins serve widely in coloration, but they are also critical compounds in metabolic pathways. In the vertebrates, the major pterin is tetrahydrobiopterin, which serves as a redox cofactor in enzymatic reactions utilizing molecular oxygen.

Biosynthesis of Neopterins and Biopterin

The synthesis of all pterins begins with the ring opening and reclosing of the nucleotide GTP by the enzyme GTP

cyclohydrolase (GTPCH). GTPCH has been isolated and sequenced from many sources. It is a decamer, each active site containing a zinc atom. As the rate-limiting enzyme of pterin biosynthesis, it is carefully regulated, both by transcriptional and posttranslational mechanisms. The catalytic domains of the *E. coli* and human enzyme are 37% identical in amino acid sequence, testifying to the ancient status of pterins in the living world.

The reaction catalyzed by GTPCH is shown in Figure 2. The purine ring system of guanine supplies all but two of the carbons in the ring system of pterin. The ribose moiety of GTP supplies the two new carbons for the pyrazine ring and the carbons of the erythrose side chain; one carbon from the guanine ring is released as formate. The pterin product is dihydroneopterin triphosphate. In eukaryotes, dihydroneopterin triphosphate is converted to dihydrobiopterin

(Figure 3). By contrast, dihydrobiopterin is not formed in most bacteria.

The structures of biopterin and its reduced forms are shown in Figure 3. Reduction of the 7,8 double bond yields 7,8-dihydrobiopterin (a tautomer of 7,8-dihydropterin is quinonoid dihydropterin). Further reduction at the 5,6 double bond gives tetrahydrobiopterin.

Pterins in Metabolism

The Aromatic Amino Acid Hydroxylases

One of the most-studied processes involving biopterin is the hydroxylation of the aromatic amino acids. This is catalyzed by a small family of enzymes containing phenylalanine (PheH), tyrosine (TyrH), and tryptophan (TrpH) hydroxylase. They contain an iron atom and utilize tetrahydrobiopterin and molecular oxygen to hydroxylate a fairly unreactive entity, an aromatic ring. The aromatic amino acid hydroxylases (AAHs) are only active in the Fe(II) state; one role of the tetrahydrobiopterin may be to keep the iron reduced. The major role of tetrahydrobiopterin is to activate the oxygen for eventual transfer to the aromatic amino acid substrate, probably through formation of a C4a-peroxy pterin intermediate (Figure 4).

Each of the AAHs catalyzes the rate-limiting step in its metabolic pathway: PheH in phenylalanine catabolism, TyrH in synthesis of the catecholamine neurotransmitters, and TrpH in serotonin synthesis. The three enzymes are homologous to a great extent in their catalytic domains (between any two there is 60% identity and 75% similarity). These enzymes as a rule are not found in bacteria, consistent with the general absence of biopterin from prokaryotes. However, PheH has been isolated from several prokaryotes, and from one, *Chromobacterium violaceum*, the sequence is 30% identical to the catalytic domain of human PheH. Two amino acid residues which bind

Figure 1 Structures of pteridine and three pteridines.

Figure 2 The first step in the synthesis of pterins from guanosine triphosphate. The atoms of GTP are color coded to show their positions in the resulting neopterin molecule. Note that one carbon of GTP, colored green, is lost as formate.

Figure 3 Structures of bioppterin and its reduced forms.

Figure 4 Peroxypterin and carbinolamine intermediates in the hydroxylation of aromatic amino acids

tetrahydrobioppterin (in TyrH, F300 and E332) are conserved in all the AAHs studied, suggesting a central role for bioppterin in the evolution of neurotransmitters and higher nervous systems.

The pterin product of the AAHs is C4a-carbinolamine dihydrobioppterin (Figure 4). It is released from the enzyme and is returned to the state needed for amino acid hydroxylation by the action of two more enzymes, C4a-carbinolamine dehydratase and dihydropterin reductase.

Nitric Oxide Synthase

Nitric oxide synthase (NOS) is responsible for the synthesis of nitric oxide, NO. NOS utilizes tetrahydrobioppterin, NADPH, and molecular oxygen to convert L-arginine to L-citrulline and NO (Figure 5). Nitric oxide is a gas and a highly toxic compound. Due to its toxicity, short half-life (1–5 s), and diffusibility, NO serves the mammalian immune system as a killer of foreign intruders and cancer cells. It is also a cellular signal through its stimulation of cGMP synthesis.

NOSs are dimers of identical subunits. NOS contains flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), heme, and tetrahydrobioppterin. The tetrahydrobioppterin-binding site is positioned close to the heme to facilitate electronic interaction between them. The tetrahydrobioppterin-binding site is formed by residues in both subunits at the

Figure 5 Reaction catalyzed by NOS.

interface where the subunits associate; the pterin ring is sandwiched between a tryptophan residue from one subunit and a phenylalanine from the other. In contrast to the two-electron loss in AAHs, the tetrahydrobioppterin of NOS loses only one electron generating a bioppterin radical. Bioppterin remains bound to NOS before and after catalysis, another difference between NOS and the AAHs.

Molybdopterin-Containing Enzymes

A very large group of enzymes contain molybdenum (or in a few cases tungsten) in conjunction with a unique pterin, molybdopterin. These enzymes function in general to transfer oxygen to or from a physiological molecule. They can be assigned to two categories based on the reaction catalyzed. The first group, the true hydroxylases, performs hydroxylation of aldehydes or aromatic rings; some of the enzymes in this category are milk xanthine oxidase, liver aldehyde oxidase, and bacterial enzymes such as formate dehydrogenase and nicotine dehydrogenase. The second category can be subdivided into (1) sulfite oxidases and enzymes, which reduce nitrate to enable a cell to utilize ammonia, and (2) bacterial enzymes, which function as terminal respiratory oxidases.

The structures of molybdopterin and the molybdenum cofactor are shown in Figure 6. The R group in prokaryotic systems can be guanine, cytosine, adenine, or hypoxanthine; in eukaryotes it is a hydrogen. The mode of binding the molybdenum cofactor to the protein differs from protein to protein in accord with the classification described above. The enzymes of

Figure 6 The structures of molybdopterin and the molybdenum cofactor.

the xanthine oxidase group contain one single molybdenum center per enzyme subunit, the sulfite oxidase family members are likely to have one molybdenum cofactor bound to a cysteine of the protein, and the final group can contain two molybdopterin coordinated to one molybdenum, which can be coordinated to a selenium, sulfur, or cysteine. The biosynthetic pathways of these pterins have not yet been resolved.

The molybdenum enzymes are a vast enough group that a discussion of their properties is inappropriate here. In general, they contain other redox centers in addition to their pterin cofactor, such as heme, iron–sulfur clusters, and flavin. The role of the pterin is postulated to include mediation of electron transfer to the other redox active centers and modulation of the reduction potential of the molybdenum. The pterin is not considered to be oxidized and reduced during catalysis, a distinct difference between these enzymes and the NOSs and AHHs.

Tetrahydrobiopterin and Human Disease

Tetrahydrobiopterin deficiency is associated with a rare variant of hyperphenylalaninemia, which cannot be treated by the low phenylalanine diet successful for typical phenylketonuria (PKU) patients. It is characterized by a deficit of catecholamine neurotransmitters and serotonin as well (the products of the AAHs), affecting the nervous system as well as the liver. It can

be caused by mutations in GTPCH or in the enzymes which recycle dihydrobiopterin. Decreased levels of tetrahydrobiopterin in cerebrospinal fluid have also been noted in diseases such as Parkinson's, autism, depression, and Alzheimer's.

Glossary

Copper chaperone Soluble cytosolic protein that binds copper and transfer copper to other protein targets.

Cuproenzyme Enzyme that uses copper as a cofactor to perform its catalytic reactions.

Phosphointermediate Intermediate state of enzyme with a covalently bound phosphate.

P-type adenosine triphosphatases (ATPases) A class of membrane proteins that use the energy of adenosine

triphosphate (ATP) hydrolysis to transport ions across biologic membranes; unlike other ATP-driven transporters, the P-type ATPases form transient phosphointermediate.

Trafficking The process of protein changing its intracellular localization between intracellular compartments.

trans-Golgi network Terminal portion of the Golgi apparatus.

γ-Phosphate The terminal phosphate group in the chain of three phosphate moieties in ATP.

Biological Roles of Cu Pumps

Cu Pumps Are Universally Found in Biological Systems

The diverse family of P-type adenosine triphosphatases (ATPases) is composed of molecular pumps that translocate specific ions and, in some cases, phospholipids from the cytosol across cellular membranes utilizing the energy of adenosine triphosphate (ATP) hydrolysis. The Cu transporting P-type ATPases, or Cu pumps, form one of the largest phylogenetic clusters in the P-type ATPase family. Cu pumps are present in three kingdoms of life (prokaryotes, archaea, and eukaryotes), illustrating the essentiality of active Cu transport for life. In biological systems, the redox chemistry of Cu ions ($\text{Cu}^+ \leftrightarrow \text{Cu}^{2+}$) has found its productive use in electron transfer enzymes. However, the same chemistry could trigger nonspecific oxidation and radical-mediated damage. Cells and tissues avoid Cu toxicity through coordinated and well-controlled Cu transport processes: sufficient uptake, targeted delivery to specific compartments, and excretion of Cu excess. In the past decade, this homeostatic system has been a subject of intensifying scientific investigations due to accumulating evidence for the role of copper homeostasis in heart development, central nervous system (CNS) function, and tumor growth. These studies have firmly established that Cu pumps play a central role in the maintenance and regulation of Cu homeostasis.

Cu Pumps Are Essential for Human Health

Human cells express two homologous Cu pumps, ATP7A and ATP7B. ATP7A facilitates transports of Cu ions from enterocytes into a blood stream for further distribution to tissues; this represents an essential step in Cu absorption. Excess copper is removed by the liver where another Cu pump, ATP7B, facilitates the export of Cu into the bile. In both cases, Cu exits cells as a result of exocytosis of vesicles, which are filled with Cu by Cu pumps. Another important role of ATP7A and ATP7B is to deliver Cu ions to specific enzymes produced in the secretory pathway. ATP7A delivers Cu to copper-requiring enzymes such as peptidyl- α -monooxygenase, tyrosinase, lysyl oxidase,

and extracellular superoxide dismutase, whereas ATP7B delivers Cu to ceruloplasmin. The multiple roles of Cu pumps in Cu absorption, delivery to the secretory pathway, and excretion require trafficking between intracellular compartments (Figure 1). It is now well established that human Cu pumps respond to the increased Cu levels by relocating from the terminal portion of the Golgi apparatus – the *trans*-Golgi network (TGN) toward the vesicles in the vicinity of plasma membrane. Although ATP7A and ATP7B are highly homologous (having 54% primary sequence identity), their intracellular itineraries differ. For example, ATP7A in enterocytes relocates toward the basolateral membrane (the blood side), while hepatic ATP7B traffics toward the apical membrane to facilitate Cu efflux into the bile. In cells expressing both Cu pumps, they show distinct trafficking behavior (different response to copper and/or different polarity of movement), indicating that Cu pumps have specific structural elements regulating their trafficking behaviors.

Information on specific physiologic roles of ATP7A and ATP7B in tissues and cells expressing both Cu pumps is limited. Recent studies in the placenta and mammary gland indicate that in these tissues the expression and intracellular localization of Cu pumps are under hormonal control. Exposure to hormones such as estrogen and insulin stimulates trafficking of Cu pumps; the trafficking step is necessary to facilitate Cu delivery to the fetus or to return Cu to maternal circulation. By contrast, in kidneys and lungs, only one Cu pump traffics (ATP7A, and ATP7B, respectively) even though both transporters are expressed. These observations suggest that in some tissues Cu pumps may participate in copper storage by sequestering copper within the endocytic pathways rather than inducing copper export.

The human Cu pumps also play a role in cellular response to pathological conditions such as hypoxia and inflammation. Under these conditions, the cellular pathways associated with Cu pumps appear selectively activated resulting in a preferential flow of copper toward the secretory pathway. The critical role of Cu pumps in human health is best illustrated by the phenotypes of Menkes disease (MND) and Wilson's disease

Figure 1 Cu pumps play a central role in copper homeostasis in human cells. Cu ions are transported into a cell through CTR1 and then delivered by a cytosolic Cu chaperone Atox1 to Cu pumps (ATP7A and ATP7B). Cu pumps located within the *trans*-Golgi network transfer copper from the cytosol to cuproenzymes located in the lumen of the TGN. When cellular Cu is elevated, ATP7B traffics from the TGN to a vesicular compartment in proximity to the apical membrane. By contrast, ATP7A traffics to vesicles at basolateral membrane. Cu is exported from cells as a result of vesicle fusion with the plasma membrane.

(WND) which are associated with inborn mutations in *ATP7A* and *ATP7B* genes, respectively. Defects in the Cu pumps lead to copper misbalance in multiple organs, causing systemic effects with the major impact on the CNS (MND) and/or liver (WND). The MND patients display severe neurological symptoms, mental retardation, vascular defects, and other developmental problems. These pathologies reflect the low activity of Cu-dependent enzymes caused by the impaired absorption of Cu through intestine and choroid plexus. Symptoms can be lessened by Cu injections into the blood, particularly if MND is identified at the presymptomatic stage (in newborns) and if the mutant *ATP7A* retains residual copper-transport activity. Mutations that completely inactivate *ATP7A* invariably lead to patient's death.

In contrast to MND, the WND symptoms are caused by abnormal accumulation of Cu, predominantly in the liver. In the CNS, the major damage is observed in the basal ganglia. The majority of WND patients present with either hepatic or neuro-psychiatric symptoms, suggesting important functions for *ATP7B* in corresponding organs. The liver is particularly affected reflecting the dominant role of *ATP7B* as a Cu exporter in this tissue. In the liver, *ATP7B* also delivers Cu ions to ceruloplasmin, an enzyme involved in iron homeostasis. Defect in this process results in the excretion of apo-ceruloplasmin, which is inactive and easily degraded in the serum (The low ceruloplasmin level serves a diagnostic marker for WND). The major WND symptoms can be greatly diminished by reducing Cu level in the body using Cu chelators and/or Zn supplementation as Zn interferes with Cu absorption.

Recent clinical studies have uncovered a new role for Cu pumps in regulating tumor growth and the resistance of tumors to chemotherapeutic drugs. Higher levels of *ATP7A* and particularly *ATP7B* expression have been detected in solid tumors that show increased resistance to cisplatin and other platinum-containing drugs. Although the relationship between Cu pumps and drug resistance seems firmly established, the precise mechanism through which Cu pumps modulate sensitivity to chemotherapeutics remains

uncertain. It was shown that *ATP7B* directly interacted with cisplatin *in vitro* and in cells, however, binding alone does not fully account for the protective effects of Cu pumps against the drug. Similarly, cisplatin can modulate the activity of *ATP7B*. However, the transport of cisplatin by Cu pumps is inefficient, and in the presence of copper the competition between these two potential substrates is not observed. Recent studies in cells and tissues deficient in Cu pumps activity indicate that the changes in copper metabolism associated with Cu-pump inactivation result in distinct transcriptional and metabolic changes (increased proliferation, altered lipid metabolism, and increased expression of other transporters). Therefore, metabolic re-adjustments due to altered levels of Cu pumps may contribute to drug resistance through indirect mechanisms.

Cu Pumps in Prokaryotes, Plants, and Fungi

Plants also utilize Cu pumps in the processes of copper absorption, delivery, and excretion. *Arabidopsis thaliana* has four genes (*AtHMA5*, *AtHMA6*, *AtHMA7*, and *AtHMA8*) encoding Cu pumps. *AtHMA6* and *AtHMA8* are closely related and elegantly collaborate to transport Cu into chloroplasts. *AtHMA6* transports Cu from cytosol across the plastid envelope into stroma where Cu/Zn superoxide dismutase (*AtCSD2*) binds transported Cu; *AtHMA8* transports Cu from stroma into the thylakoid lumen to supply Cu to plastocyanin, an electron-transferring enzyme in the photosystem. Two Cu pumps (*CtaA* and *PacS*) of *Synechocystis*, a cyanobacterium that shares evolutionary ancestry with chloroplasts, play analogous roles. This finding suggests that the double-tiered Cu transport system was established early in the evolution of the photosynthetic system. *AtHMA7* is thought to deliver Cu ions to the secretory pathway for incorporation into the ethylene receptor (*ETR1*). A single Cu atom in an *ETR1* homodimer is required for the high-affinity binding of a hormone ethylene and initiation of signaling cascade. Mutation of *AtHMA7* results in the loss of *ETR1*-dependent ethylene signaling, likely due to the lack of bound copper. Finally, *AtHMA5* is a candidate for Cu excretion, as suggested by a hypersensitivity of plants lacking *AtHMA5* to environmental Cu.

Yeast *Saccharomyces cerevisiae* has a single Cu pump (*Ccc2p*). Similar to human Cu pumps, *Ccc2p* is located in the TGN. It transports Cu to the lumen of the secretory pathway where Cu is incorporated into *Fet3p*, a Cu-containing ferroxidase required for iron absorption. Deletion of *Ccc2* leads to inactivation of *Fet3p* and poor growth under Fe-limiting conditions. The $\Delta Ccc2$ phenotype can be rescued by gene complementation using the Cu-pump complementary DNA (cDNA) from various species. This assay has been a valuable system for evaluation of Cu pumps transport activity. However, *Ccc2p* does not traffic from TGN or contribute to Cu export, indicating the important difference of Cu homeostasis between yeast and mammals. Cu homeostasis varies even among yeast strains. *Candida albicans*, a strain with high resistance to Cu, has a second Cu pump, *CRP1p*. *CRP1p* is expressed at the plasma membrane, excretes Cu ions from the cell, and contributes to high resistance against environmental Cu.

In prokaryotes, Cu pumps together with pumps for other transition metals (Zn, Pb, Cd, Co, and Ni) are the predominant

P-type pumps. *Enterococcus hirae* was the first model organism to study Cu homeostasis. A Cu-responsive operon in this bacterium harbors two genes for Cu pumps (CopA and CopB). CopA is thought to act as a Cu importer because cells lacking CopA cannot grow in the Cu-depleted media, while CopB exports Cu from the cell and is involved in Cu resistance. CopA homologs are present in plasma membrane of many other bacteria and archaea; most of them have Cu-export activities (unlike *E. hirae*) typically utilized to confer resistance to Cu. The homologs from various thermophiles (*Archaeoglobus fulgidus*, *Sulfolobus solfataricus*, *Aquifex aeolicus*, and *Thermotoga maritima*) have been successfully used in recent structural studies (see below).

Molecular Architecture and Functions of Cu Pumps

Characteristics of the P-type ATPases Shared by the Cu Pumps

Cu pumps share the general mechanism and architecture with other P-type ATPases. A typical Cu pump is a membrane protein with the N- and C-termini both oriented toward the cytosol. The α -helical transmembrane (TM) part of Cu pumps is involved in copper translocation, while ATP hydrolysis is mediated by its cytosolic domains (Figure 2). The majority of Cu pumps transport Cu ions in the outward direction (from the cytosol into a lumen or extracellular milieu) and follow the reaction cycle common to all P-type pumps, which is known as 'Post-Albers cycle'. According to this cycle, the pump assumes two major ground conformations, E1 and E2. The intramembrane Cu-binding sites have cytosolic access and high affinity in E1 while they have luminal access and low affinity in E2. Cu ions enter these binding sites from the cytosol in E1, become occluded after ATP hydrolysis and transient auto-phosphorylation (E1P intermediate), and jettisoned into the lumen during a subsequent protein isomerization to E2P. The phosphorylated intermediate is then cleaved through auto-dephosphorylation, generating E2 for the next reaction cycle. The ability of Cu pumps to hydrolyze ATP and form a

phosphorylated intermediate in a copper-dependent manner has been directly demonstrated. Extensive studies of the sarcoplasmic reticulum Ca^{2+} pump (SERCA) revealed a strikingly sophisticated domain movement underlying ATP-driven transport of Ca^{2+} . Recent analysis of Cu pumps has demonstrated similar domain movements that suggest the analogous pumping mechanisms for Cu and other P-type pumps.

Overall structure of Cu pumps is similar to other P-type ATPases, which is apparent from the low-resolution maps generated using the 2-D crystals of bacterial/archaeal Cu pumps (*Aquifex aeolicus* CtrA3 and *A. fulgidus* CopA). Cytosolic loops form four separate domains including the N-terminal metal-binding domain (N-MBD) and three domains common for all P-type pumps: A (actuator) domain, N (nucleotide-binding) domain, and P (phosphorylation) domain. The P and N domains are located between TM6 and 7, forming the catalytic core. The structure of the P domain (determined for CopA) is almost identical in all P-type pumps. It has a typical Rossmann fold with a parallel β -sheet sandwiched by short α -helices. During catalysis, the γ -phosphate of ATP is transferred to the carboxyl group of the invariant Asp located at the end of the central β -strand of the P-domain, producing transient phosphointermediates (i.e., E1P and E2P in the reaction scheme). The functionally important sequence motifs, DKTGTLT (phosphorylation site) and GDGXND (Mg^{2+} coordinating site), are invariant in the P-type pumps. The geometry of these key residues is preserved within haloacid dehalogenase (HAD) superfamily to which P-type ATPases belong, reflecting the importance of this arrangement for nucleophilic reactions catalyzed by the HAD superfamily members. The N domain is inserted in the P domain and consists of an antiparallel β -sheet sandwiched by two pairs of α -helices. This global fold is shared by all P-type pumps despite limited sequence homology. The N domain forms a docking site for the adenosine moiety of ATP. The A domain is located between TM4 and 5 and is composed of antiparallel β -strands with a β -hairpin structure. The A domain has a Gly-Glu motif (an invariant part of a more variable TGES motif), which is involved in

Figure 2 The major functional domains of human Cu pumps. The transmembrane portion of a Cu pump is composed of eight transmembrane segments (colored in spectrum, red to blue, according to their order from the N-terminus) that form two intramembrane copper-binding site(s) contributed by the sequence motifs, CPC, YN, and MxxS. The cytosolic catalytic core is composed of the P-domain (magenta) and the N-domain (green) and, together with the A-domain (turquoise), is responsible for enzymatic cycle (ATP binding, hydrolysis, phosphorylation, and dephosphorylation). The N-terminal domain has six metal (Cu)-binding subdomains (MBD1–6, light magenta). (Left inset) The structure of MBD1 with a Cu atom bound in the GMxCxxC motif. (Right inset) The local environment around bound ATP highlighting residues essential for binding. For clarity, some structural elements are not shown. The blue dot near the ATP indicates Mg^{2+} ion.

dephosphorylation ($E2P \rightarrow E2$), and may actuate rearrangement of connected TM helices, as in other pumps.

Distinct Functional Properties of Cu Pumps

Cu pumps have evolved to accommodate unique properties of Cu (particularly Cu^+) that are markedly different from those of other ions transported by the P-type pumps. First, Cu^+ prefers sulfur as a coordinating atom, whereas hard metal ions are predominantly associated with oxygen atoms. Generally, Cu^+ -sulfur interaction is stronger than the hard metal-oxygen interaction. This explains extremely high affinity observed for various Cu^+ -binding proteins including Cu pumps. Measurements for archaeal Cu pump CopA shows an apparent affinity of 1.1 fM^{-1} for one of the two intramembrane Cu-binding sites. The mechanism through which Cu pumps disassemble such an extremely stable binding site to dissociate bound Cu is presently unknown. A drastic conformational change, protonation by low luminal pH, and/or assistance of Cu-acceptor molecules may conceivably facilitate copper release.

Second, unlike H^+ , Na^+ , K^+ , Ca^{2+} , or Mg^{2+} , free Cu ions are mostly unavailable in the cytosol. In yeast, the number of free Cu ions was calculated to be below one per cell. In eukaryotes, cytosolic Cu exists largely in a complex with proteins including Cu chaperones, which carry Cu ions to specific protein acceptors. The human Cu pumps are thought to receive their Cu from the copper chaperone Atox1. This step is important but not obligatory for their activity, because the phenotype of mice lacking Atox1, although reminiscent of ATP7A loss, appears milder than that of mice lacking the Atox1 downstream targets ATP7A and ATP7B. Also, ATP7A senses copper and traffics in the *Atox1*^{-/-} cells, although with slower kinetics compared to control. Current data indicate that Atox1 transfers copper to the N-MBD of human Cu pumps, but little information is available on how copper reaches the TM Cu-binding sites.

Third, the turnover of Cu pumps is strikingly slower compared to other ion-pumping P-type ATPases ($\sim 30 \text{ s}^{-1}$ for Ca^{2+} pump and $0.1\text{--}3 \text{ s}^{-1}$ for Cu^+ pump). This may not be surprising since the Cu pumps do not generate significant ion gradients and their major role is to deliver copper for further utilization by the enzymes, which are synthesized at limited quantities and with defined kinetics. It is thought that the turnover of Cu pumps is regulated by their unique N-terminal domain. This domain is present in all Cu pumps, and it influences their reaction cycle via copper binding and copper-dependent interactions with other domains. Mutation and deletion of the N-terminal domain have different consequences on the reaction cycle in Cu pumps from different species, although the decrease of Cu transport activity is common.

Finally, unlike other P-type pumps which work predominantly in a single cellular location (plasma membrane, endoplasmic reticulum, and secretory pathway), the mammalian Cu pumps traffic within the cell and function in different intracellular compartments. Regulated trafficking allows Cu pumps to switch from their function in the biosynthesis of cuproenzymes to copper export and protection of cells from copper overload. Studies of the trafficking mechanism have identified several factors involved in regulation of this process

and suggested an important link between the Cu transport and a kinase-mediated signaling. The unique molecular functions of Cu pumps and their regulation can be better understood if one considers the unique structural elements of Cu pumps and compares those to other P-type pumps.

Unique Structural Features of Cu Pumps

TM domain. The TM domain is the place where ions are selectively bound, occluded, and then released in a vectorial manner. Therefore, this domain is the fundamental component of the ion-pumping machinery. The TM domain consists of 10 helices in most P-type pumps; however, the transition metal pumps including Cu pumps have eight TM helices. The membrane topologies and the estimated arrangements of the TM helices in the two-dimensional projection maps suggest that TM3–TM8 of the Cu pump are counterparts of TM1–TM6 of other P-type pumps. The TM1, 2 hairpin is specific to transition metal pumps. In Cu pumps, it frequently contains Met and His residues suggestive of copper-binding role, though their actual function is yet to be explored. High-resolution model of Cu pumps is not yet available; however, a detailed sequence analysis and mutagenesis using CopA from *A. fulgidus* determined that the Cu pumps have two Cu-binding sites in the TM region. Site I is constituted by Cys/TM6, Cys/TM6, and Tyr/TM7; while site II constituted by Asn/TM7, Met/TM8, and Ser/TM8. Consistent with this predicted coordination, the EXAFS spectra of bound Cu ions indicated trigonal geometries and the participation of nitrogen/oxygen atoms as well as sulfur. The residues predicted to coordinate copper are conserved within Cu pumps including human homologs (ATP7A and ATP7B). Mutation of Ser/TM8 of ATP7B has been identified with the WND phenotype.

Cytosolic catalytic domains. The N domain of a Cu pump (and other transition-metal pumps) is distinguished by the unique amino acid sequence and the distinct mode of nucleotide recognition compared to other P-type ATPases. The solution structure of the N domain of ATP7B pointed to residues forming the ATP-binding pocket (H1069, G1099, G1101, I1102, G1149, and N1150) as these residues showed chemical shifts upon binding of nucleotide. The ATP-coordinating residues are highly conserved in all Cu pumps but differ from the ATP-coordinating residues of other P-type pumps. Such difference in coordination environment may explain a tighter binding of nucleotide by the isolated N domain of ATP7B compared to the N domains of other P-type pumps and may contribute to a slow turnover rate of Cu pumps during their reaction cycle. Recently, the coordination environment and the position of ATP in the pocket became crystal clear with two atomic models of nucleotide-bound forms (archaea CopA and ATP7A). These studies highlighted an important role of the conserved Glu (in the ExSEHPL motif), which was found hydrogen bonded with the adenine ring.

The structures of the A domains of archaea (*A. fulgidus* CopA) and human ATP7A revealed their high similarity to those of other P-type pumps. However, the A domains of other P-type pumps in addition to a central β -sheet/ β -hairpin contain a small α -helical element. In SERCA, this α -helical part transmits the movement of the A domain to the TM helix regulating the cytosolic gating of the ion path. The Cu

pumps apparently lack this important helical element. This difference raises a question as ‘how do the Cu pumps regulate the gating of the ion path? Is there a gating?’ One suggested possibility is that the N-MBD associates with the A domain and substitutes the missing α -helical part with one of its helices.

N-terminal metal-binding domain. The N-MBD is a characteristic component of Cu pumps, which is involved in regulations of catalytic activity and protein trafficking. This domain is composed of one to six (mammalian Cu pumps) homologous subdomains. Each of the subdomains is, typically, 70–80 amino-acid residues long, has a ferredoxin-like $\beta\alpha\beta\beta\alpha\beta$ -fold, and houses a single Cu-binding site GMxCxC, in which two invariant Cys residues coordinate Cu(I). Cu binding induces rearrangement of the subdomains, which can be readily visible in different proteolytic patterns (limited proteolysis is often used to detect a conformational change) or by circular dichroism spectroscopy. In human Cu pumps, the tight packing of six N-terminal MBD is responsible for the maintenance of the reduced state of the Cu-binding sites and for conformational transitions of the entire domain in response to copper binding. In eukaryotic pumps, the NMBD is thought to serve as a docking site for copper chaperone Atox1. Copper transfer from Atox1 to N-MBDs initiates the transfer of copper to the TM domain. In archaeal CopA, the direct delivery of copper to the TM domain by the copper chaperone copZ was also shown.

Regulation of Mammalian Cu Pumps

Regulations of Cu Pumps via Trafficking

Copper chaperone Atox1 is likely to sense cytosolic copper and regulate copper occupancy of Cu pumps. Atox1 and N-terminal metal-binding subdomains have the same fold and the Cu-binding motif (GMxCxC). *In vitro*, Atox1 and the NMBD interact with each other and exchange bound Cu ions. The Cu-Atox1 complex stimulates the Cu-pump activity, while apo Atox1 removes copper from NMBD and downregulates Cu pump. The Atox1-mediated regulation of copper binding allows NMBD to assume different conformations which may be central for further regulation.

In response to the elevation of cellular Cu, the mammalian Cu pumps traffic from the TGN to vesicles and during vesicle fusion reach the plasma membrane (Figure 1). This process is reversible and Cu pumps return back to the TGN when copper levels decrease. So far, three major targeting motifs have been identified in human Cu pumps. The LL or LLL motifs in the protein C-termini play a role in endocytic retrieval of Cu pumps from the plasma membrane (ATP7A), as well as the exit from the TGN. The C-terminus of ATP7A, but not ATP7B, has a putative PDZ-binding motif, DTAL, which is required for the basolateral targeting. By contrast, ATP7B contains the FAFDNV-GYE sequence, which is an essential apical-targeting determinant and is located in the N-terminal segment before the first metal-binding site.

The mechanism through which changing Cu levels regulate the trafficking of Cu pumps is not fully understood, although conformational changes in Cu pumps in response to copper binding were reported. Mutagenic studies demonstrated that the loss of transport function results in the loss of trafficking,

indicating that the binding of ligands and/or saturation of lumen with copper play a significant role in the Cu pumps exit from the TGN. The trafficking ability of inactive mutants can be restored by trapping the pump in a specific conformation; however, in such mutants the sensitivity to Cu appears altered or lost resulting in constitutive trafficking under basal conditions. The current data are best accommodated by the model, where elevated Cu triggers conformational change in the NMBD, which stimulates the Cu-pump activity and induces further structural changes in the pump-making sites available to trafficking machinery. Lumenal signaling by copper (under conditions of saturation) may also contribute to the trafficking from the TGN. Also, other signals/pathways contribute to trafficking response. Insulin and estrogen promote ATP7A trafficking, but suppress ATP7B trafficking in placental cells; while activation of the N-methyl-D-aspartate (NMDA) receptor promotes trafficking of both ATP7A and ATP7B in hippocampal neurons, presumably by facilitating Ca^{2+} -dependent vesicle fusion. Current evidence suggests that kinase-mediated phosphorylation could be one of the unifying pathways that regulates trafficking of mammalian Cu pumps.

Kinase-Mediated Phosphorylation of Mammalian Cu Pumps

Kinase-mediated phosphorylation was reported for both ATP7A and ATP7B, and the current data point to the important role of kinase-mediated phosphorylation in regulating the activity and intracellular localization of these Cu pumps. Mammalian Cu pumps are phosphorylated at Ser residues by Mg^{2+} /ATP-dependent kinases in basal conditions and in response to the increase in the intracellular Cu level. Mass-spectrometric analysis of ATP7A and ATP7B identified multiple phosphorylation sites, located predominantly in the NMBD and C-terminus of Cu pumps. Specific function of each phosphorylation site remains to be explored; however, in ATP7A mutation of C-terminal phosphorylation sites results in mislocalization of Cu pumps. It is interesting that the kinase-mediated phosphorylation appears to be coupled to catalytic phosphorylation, a finding that may link together several events that lead to Cu pump exit from the TGN: copper binding, stimulation of transport, and phosphorylation.

Glossary

Gastric H⁺,K⁺-ATPase An enzyme, which is one of the P₂-type ion-motive ATPases, that allows an electroneutral exchange of cytoplasmic protons for extracytoplasmic potassium.

α-Subunit of gastric H⁺,K⁺-ATPase Functional subunit consisting of 1034 amino acids with an M_r

of 114 kDa, which has 10 transmembrane segments.

β-Subunit of gastric H⁺,K⁺-ATPase A glycoprotein consisting of ~290 amino acids having one transmembrane segment and six or seven N-linked glycosylation sites in the extracytoplasmic region.

The gastric H⁺/K⁺ pump is a member of the P₂-type ion-motive adenosine triphosphatase (ATPase) family and is responsible for the elaboration of HCl by the parietal cell of the gastric mucosa. The gastric H⁺,K⁺-ATPase catalyzes H⁺ for K⁺ exchange by an electroneutral exchange of cytoplasmic protons for extracytoplasmic potassium, while the protein undergoes phosphorylation and dephosphorylation related to ion binding and release. The gastric H⁺,K⁺-ATPase is composed of two subunits, the catalytic or α-subunit having 10 transmembrane segments and the β-subunit having 1 transmembrane segment. The gastric H⁺,K⁺-ATPase α-subunit is a 100-kDa protein consisting of ~1034 amino acids and β-subunit is a glycoprotein with ~290 amino acids.

Structure of the Gastric H⁺,K⁺-ATPase

The α-Subunit of Gastric H⁺,K⁺-ATPase

The primary sequences of the α-subunits deduced from complementary DNA (cDNA) have been identified from pig, rat, and rabbit. The hog gastric H⁺,K⁺-ATPase α-subunit sequence deduced from its cDNA consists of 1034 amino acids with an M_r of 114 285 Da. The rat gastric H, K ATPase consists of 1033 amino acids with an M_r of 114 012 Da, and the rabbit gastric H, K ATPase consists of 1035 amino acids, showing an M_r of 114 201 Da. The degree of conservation among the α-subunits is extremely high (over 97% identity) among species. The gene sequence for human and the 5' part of the rat H⁺,K⁺-ATPase α-subunits have been determined showing that the human gastric H⁺,K⁺-ATPase gene has 22 exons and encodes a protein of 1035 residues including the initiator methionine residue (M_r = 114 047 Da). These H⁺, K⁺-ATPase α-subunits show high homology (~60% identity) with the Na⁺, K⁺-ATPase catalytic α-subunit. The putative distal colon H⁺,K⁺-ATPase α-subunit has also been sequenced and shares 75% homology with both the H⁺,K⁺- and Na⁺, K⁺-ATPases.

The gastric H⁺,K⁺-ATPase α-subunit has conserved consensus sequences along with the other P type ATPases, the sarcoplasmic reticulum Ca²⁺-ATPase and the Na⁺, K⁺-ATPase, for the ATP-binding site, the phosphorylation site, the pyridoxal 5'-phosphate-binding site, and the fluorescein isothiocyanate-binding

site. These sites are thought to be within the ATP-binding domain in the large cytoplasmic loop between transmembrane segments 4 and 5. Structurally, this enzyme can be divided into three domains, namely, cytoplasmic, membrane, and extracytoplasmic domains. The cytoplasmic domain contains four subdomains, a stalk domain, N-domain, P-domain, and A-domain. The N-domain or nucleotide-binding domain is a large cytoplasmic domain between M4 and M5 where ATP binds. The P-domain or phosphorylation domain is a cytoplasmic domain near M4 where there is phosphorylation and dephosphorylation. The A-domain or activation domain is a cytoplasmic domain between M2 and M3, which moves depending on conformational changes. The stalk domain contains the extension of the transmembrane segments into the cytoplasmic region and forms a link for the passage of ions into the membranes and for transmission of conformational changes from the cytoplasm. The gastric H⁺, K⁺-ATPase structure is shown in [Figure 1](#), based on a 6.5-Å resolution of two-dimensional (2D) crystals reported by Abe et al. in 2009.

There are 10 transmembrane segments in the H⁺,K⁺-ATPase α-subunit. The first four transmembrane pairs connected by their luminal loop were detected in a tryptic digest of the hog gastric H⁺,K⁺-ATPase. A peptide fragment beginning at gln¹⁰⁴ represents the H1/loop/H2 sector. The H3/loop/H4 sector was found at a single peptide peak beginning at thr²⁹¹, and the H5/loop/H6 sector at a peptide beginning at leu⁷⁷⁶. The H7/loop/H8 region was found in a single peptide fragment of 11 kDa, beginning at leu⁸⁵³.

Antibody 95 inhibits ATP hydrolysis in the intact vesicles, and appears to be K⁺ competitive. The sequence recognized by this antibody was between amino acid positions 529 and 561. As it inhibits the enzyme in intact cytoplasmic side out vesicles, this epitope must be cytoplasmic and it is close to the region known to bind the cytoplasmic reagent, fluorescein isothiocyanate, a lysine reagent, in the loop between H4 and H5. Antibody 1218 was shown to have its major epitope between amino acid positions 665 and 689 in the same N domain. A second epitope for mAb 1218 was also identified to be between amino acid positions 853 and 907. The monoclonal antibody 146 epitope was defined to be between positions 873 and 877 of the hog α-subunit. This is on or close to the extracytoplasmic face of H7.

Figure 1 Proposed structure of the gastric H^+,K^+ -ATPase. (a) The α -subunit has three lobes, N (ATP binding), P (phosphorylation), and A (activation) regions in the cytoplasmic domain, and 10 transmembrane segments in the membrane domain. The gastric β -subunit has one transmembrane segment and a heavily glycosylated extracellular region. (b) Conformational changes of gastric H^+,K^+ -ATPase α -subunit. With binding of H^+ and MgATP to the E_1 form, there is transient association of the N and P lobes with phosphorylation of asp386 and a conformational change to E_2P so that the A domain associates with the P domain. This change is transmitted to the membrane domain in the region of TM6 (dark yellow) and H^+ binding to the cation-binding domain in the middle of the membrane domain is followed by release of H^+ and binding of K^+ from the luminal surface. There is then dephosphorylation and reformation of the E_1 conformation with release of K^+ to the cytoplasm.

The β -Subunit of Gastric H^+,K^+ -ATPase

The primary sequences of the β -subunits have been reported for rabbit, hog, rat, mouse, and human. The β -subunit with ~ 290 amino acids is a glycoprotein having one transmembrane segment located at the region between amino acid sequence positions 38 and 63 near the N terminus and six or seven N-linked glycosylation sites in the extracytoplasmic region. Using lectin-affinity chromatography, the H^+,K^+ -ATPase α -subunit was co-purified with the β -subunit, showing that the α -subunit interacts with the β -subunit. By cross-linking with low concentrations of glutaraldehyde, the β -subunit was shown to be closely associated with the α -subunit. In the extracytoplasmic domain, there are six cysteines that are linked through disulfide bonds. Reduction of the disulfides of the β -subunit inhibits the activity of the H^+,K^+ -ATPase. In the case of the Na^+,K^+ -ATPase, the effect of reducing agents on the ability of the enzyme to hydrolyze ATP and bind ouabain was quantitatively correlated with the reduction of disulfide bonds in the β -subunit. Seven putative N-glycosylated sites (AsnXaaSer and AsnXaaThr) are shown in rabbit H^+,K^+ -ATPase β -subunit, which are conserved in rats and humans. Six putative N-glycosylation sites are found in the hog gastric β -subunit. The N-linked oligosaccharides of the β -subunit of rabbit gastric H^+,K^+ -ATPase were identified. All N-linked AsnX(Ser/Thr) sequences at positions 99, 103, 130, 146, 193, and 222 were fully glycosylated. Asn 99 was modified exclusively with oligomannosidic-type structures, $Man_6GlcNAc_2$ – $Man_8GlcNAc_2$, and Asn193 has $Man_5GlcNAc_2$ – $Man_8GlcNAc_2$ and lactosamine-type structures. Asn 103, 146, 161, and 222 contain lactosamine-type structures. All the branches of the lactosamine-type structure were terminated with $Gal\alpha$ – $Gal\beta$ – $GlcNAc$ extensions. The role of the carbohydrate chains was studied using HEK-293 cells. The enzyme activity

was not affected by removal of any one of seven carbohydrates of the β -subunit; however, removal of all carbohydrate chains resulted in the complete loss of activity. Except for the second glycosylation site, each site was essential for trafficking from Golgi to plasma membrane, but not for endoplasmic reticulum to Golgi movement.
